The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 Fifteenth St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Michel A. Ibrahim, MD, PhD, Editor, *American Journal of Public Health,* 1015 Fifteenth St., NW, Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication and are not under consideration elsewhere.

Subscription price, individual, is $80/year US, $120/year international; **institutional,** $160/year US, $240/year international. Single copies $10 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 Fifteenth St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters.

Advertising Sales: Mary Beth Kammann, Advertising Manager, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal of APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact: Marilyn Butler, AJPH Reprints, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols. 1 to present are also available on microfilm.

Copying done for other than personal or internal reference use—such as copying for general distribution, for advertising or promotional purposes, for creating new collective works, or for resale—without the expressed permission of the American Public Health Association is prohibited. Requests for special permission or bulk orders should be addressed to APHA headquarters.

The American Journal of Public Health is indexed in whole or in part in these data bases: Bibliographic Index of Health Education Periodicals, Biological Abstracts, Biology Digest, BRS Bibliographic Retrieval Service Inc, Chemical Abstracts, Cumulative Index to Nursing & Allied Health Literature, Environmental Information Center Inc., Environmental Periodicals Bibliography, Excerpta Medica, Grateful Med, Hospital Literature Index, Hospital Management Review, Human Resources Abstracts, Index Medicus (Abridged), MEDLARS, MEDSOC, Nuclear Science Abstracts, Physical Education Index, Public Affairs Information Service, Public Health Reviews, Safety Science Abstracts, Sage Family Studies Abstracts, Science Citation Index, and Social Work Research and Abstracts.

Language of Interview: Relevance for Research of Southwest Hispanics

Bradford Kirkman-Liff, MS, DrPH, and Delfi Mondragón, MHS, MPH, DrPH

ABSTRACT

Background. This paper reports the results of a survey investigating health status, access, satisfaction with care, and barriers to care in Arizona. The major focus is on the association between language of interview and the dependent measures; interviews were conducted in English and Spanish.

Methods. The differences between groups were tested using chi-square statistics for each independent categorical variable; the significance of all the independent variables on each of the dependent variables was tested simultaneously using maximum likelihood logistical regression models.

Results. Language of interview for Hispanic children was a significant variable, more important than ethnicity itself, in determining health status, access, satisfaction with care, and barriers to care; language of interview for Hispanic adults was not a significant measure, but neither was ethnicity. Instead, income affected access to care for adults.

Conclusions. This pattern of results suggests that in the southwestern United States, studies on health status and access to care that use only ethnicity and do not include language of interview may fail to identify populations of Hispanic children who are remarkably more vulnerable. Public health research of Hispanic populations can be more instrumental toward policy improvement if it increases its specificity with this heterogeneous group. Analysis of language of interview has a low cost and a high benefit toward this specification. (*Am J Public Health.* 1991;81: 1399–1404)

Introduction

The health of Hispanic Americans has attracted public health research interests for important reasons: poor health status,[1,2] diminished routine use of care,[3–6] and increasing, unprecedented violence.[7,8] The most dominant contextual variables for health, level of income and education, are the lowest in the nation.[9] Moreover, Hispanic population growth exceeds that of all other racial and ethnic groups.[10] In addition to underscoring important empirical issues, methodological inquiries have addressed data uniformity,[11–16] identifier terminology[17–20] and its implications for policy,[21] effects of acculturation,[22,23] and comparative validity of translation.[24–26]

An operationalization for measurement that adds not only to methodological study but to the inferences drawn is language of interview. Among 69 articles published on the topic in the last 10 years, we found none that treated the language of the interview as an analytical variable, even though direct questions about English proficiency and proficiency as a measure of acculturation have been used. Language of interview contributes to specification in research of US Hispanics, particularly in the Southwest, because Hispanics have great genetic, historical, socioeconomic, and political heterogeneity. Furthermore, English language ability sufficient for an interview is often an indirect measure of ability to obtain other health inputs, such as employment, housing, education, nutrition, and health care.

Methods

The data were drawn from a larger survey, commissioned by a major Arizona foundation, investigating health status, barriers to health care, and satisfaction with care in the state. The field work was conducted by Louis Harris and Associates, Inc, using a questionnaire and survey design developed by the investigators, provider and consumer groups, and government agencies in Arizona. The survey was designed to provide reliable information about a representative cross-section of adults and children in all parts of Arizona, excluding those whose places of residence were Indian reservations, military bases, prisons, nursing homes, college dormitories, and mental institutions.

The total survey consisted of 3104 randomly selected adults 17 years of age and over who were interviewed about themselves, and 1113 adults who provided information about a randomly selected child 0 to 16 years of age living in the household. Of the 4217 interviews, 4073 were conducted by telephone during February through May of 1989. In the first stage, interviews were conducted with a representative cross-section of 2000 adults and on behalf of 705 children; in the second stage, additional telephone interviews were conducted with 1004 adults and on behalf of 364 children at or below the poverty level. The child proxy was identified by asking the adult respondent for the

This paper was submitted to the journal July 18, 1990, and accepted with revisions May 28, 1991.

identity of the adult in the household who was most familiar with the health care of the child. If this was the adult respondent, then the interview continued; if not, then the interview shifted to that identified person. The oversample was obtained by screening additional households drawn from the same bank of telephone numbers in which low-income persons had been found in the first stage. A household was not interviewed if its income exceeded the poverty level. In both stages of the telephone interviews, rural areas were oversampled to provide better data about less-populated areas, whereas Maricopa County, with 83% of the population, was undersampled.

Lastly, 144 in-person interviews were conducted in households without telephones (100 with adults about themselves and 44 with adults about their children) in order to obtain responses from those populations least likely to have residential telephones—poor, Spanish-speaking Hispanics. These in-person interviews were conducted in selected census tracts in Phoenix, Tucson, and Yuma that had the lowest proportion of households without telephones and the highest proportion of households below the federal poverty line. This resulted in Spanish speakers being more likely to receive a personal interview than English speakers. Hispanic adults accounted for 50% of the in-person adult interviews, compared with 19% of the telephone interviews, before weighting. Hispanic children accounted for 55% of the in-person child interviews, compared with 26% of the telephone interviews, before weighting. This was done to preclude bias from using only telephone interviews, with subsequent underreporting for those without telephones; there are no publicly available data on urban/rural and Hispanic/Anglo telephone penetration rates for simple weighting procedures. We chose instead the documented but smaller potential risks of administration effects of face-to-face[27,28] and different-language interviews.[25] The questionnaire was translated from English to Spanish by consultants in Tucson in order to use appropriate phraseology, and retranslated by other consultants to verify the accuracy of the translation, for both telephone and in-person interviews.

A total of 469 adults and 235 children who labeled themselves Mexican American or Hispanic were identified. They were asked whether they preferred to be interviewed in Spanish or English. Of these, 139 adult interviews and 70 child interviews were conducted in Spanish. All of the tabular analyses reported were performed using weighted observations.

Dependent measures used for recipient health status and access to care were as follows:

- *Current health status:* whether the respondent was in excellent, good, fair, or poor health
- *Disability:* whether the respondent was disabled, handicapped, or had a chronic disease that kept him or her from participating fully in work or other activities
- *Usual source of care:* whether the respondent had one person or place that he or she usually went to when sick or when seeking advice about health
- *Medical care use:* whether, in the 12 months prior to the survey, the respondent had one or more visits to a medical provider and (separately) one or more visits for emergency care
- *Nonreceipt of needed care:* whether the respondent, in the 12 months prior to the survey, thought that he or she needed medical care but did not receive it
- *Refusal of medical care:* whether the respondent, in the 12 months prior to the survey, had been refused health care because of financial or other reasons
- *Access to care:* whether it had become easier or more difficult for the respondent and his or her family to get the medical care they needed
- *Financial problems from illness:* whether illness in the family had been a major financial problem.

The last four items were used only in the adult respondent interviews.

This analysis used the following independent measures:

- *Ethnicity:* Anglo or Hispanic, derived from two separate questions (The term *Anglo* was used as a convenient way of referring to the non-Mexican dominant society, not necessarily indicating British origin. Respondents were asked for their race, from among the categories of White, Black, Asian, Native American, or other. Those who reported "other" were asked for their race: the most common answer was Mexican American, which was recorded. Respondents were separately asked whether they were Hispanic. Individuals who were White and not Hispanic were classified as Anglo, and individuals who identified themselves as Mexican American or White and Hispanic were classified as Hispanic. For the purpose of this analysis, Black and Native American respondents were excluded from all calculations.)
- *Language of interview:* the language in which the interview was completed, recorded separately
- *Employment status of the main wage earner in each household:* whether the main wage earner was employed, unemployed, or not in the labor force (retired, full-time student, homemaker, or disabled)
- *Household income:* classified as poor (below the federal poverty definition), near poor (between federal poverty and 185% of the poverty line), and non-poor (over 185% of federal poverty)
- *Age of adult respondents:* 17 through 39, 40 through 64, and 65 and older
- *Education of the adult respondent and the main wage earner in each household:* less than a high school education, a high school education, or more than a high school education
- *Residence:* urban (Maricopa or Pima Counties, which include Phoenix and Tucson) or rural Arizona
- *Mode of interview administration:* telephone or in-person

In an exploratory stage, statistical significance of the differences between groups for the reported measures was tested using chi-square statistics for each independent categorical variable. In the final analyses, maximum likelihood logistical regression models were developed that simultaneously tested the significance of all of the independent variables on each of the dependent variables. This process involved forward model construction, to control for possible confounding due to the paucity of independence among variables themselves. In all of these models, the ethnicity and language of interview terms were included to test for their significance, after controlling for all other significant demographic measures. Dummy variables representing different categories within each of the demographic variables were used in the logistical models.

Results

The exploratory cross-tabulations for the nine health status and access measures for adults revealed significant differences between Anglos and Hispanics on seven of these measures, at a 95% confidence level. (These tables can be obtained from the second author.) Six of these measures indicated that Hispanics in Arizona have

lower health status and worse access to care than Anglos, before consideration of other demographic variables. These measures included the proportion whose self-described health status was fair or poor, the proportion without a usual source of care, the proportion without an ambulatory care visit in the 12 months prior to the survey, the proportion who sought but were refused care, the proportion whose access to care had become more difficult, and the proportion with financial problems due to illness. The comparison of Hispanics interviewed in English with those interviewed in Spanish revealed that there are significant differences between these two groups on five of these measures. All five of these comparisons indicate that the Hispanics who were interviewed in Spanish have lower health status and worse access to care than Hispanics who were interviewed in English, before consideration of other demographic variables. These measures included the proportion whose self-described health status was fair or poor, the proportion without a usual source of care, the proportion without an ambulatory care visit in the 12 months prior to the survey, the proportion who sought but were refused care, and the proportion with financial problems due to illness.

Similar results were found for the five health status and access measures for children. There are significant differences between Anglos and Hispanics on two of the measures, at a 95% confidence level: the proportion whose proxy-described health status was fair or poor and the proportion who were disabled. Both of these measures indicate that Hispanic children in Arizona have lower health status than Anglos but no worse access to care, before consideration of other demographic variables.

The comparison of Hispanic children whose parents were interviewed in English with those whose parents were interviewed in Spanish indicated that there are significant differences between these two groups on three of these measures. All three of these comparisons indicate that the Hispanic children whose parents were interviewed in Spanish have lower health status and worse access to care than Hispanic children whose parents were interviewed in English, before consideration of other demographic variables. Two of these measures—percentage of children with no usual source of care and percentage of children with no ambulatory care visit in the 12 months prior to the survey—showed no difference between Anglos and

all Hispanics but significant differences between those children with English- and Spanish-speaking Hispanic parents. The third measure was the proxy-reported health status, which showed a gradient of declining health status from Anglo children, through Hispanic children with English-speaking parents, to Hispanic children with Spanish-speaking parents.

Analysis of the demographic measures for adults showed significant differences between Anglos and all Hispanics on all six demographic measures and significant differences between Hispanics interviewed in English and those interviewed in Spanish on three measures. There were significant differences between Anglo and all Hispanic children on all four demographic measures and significant differences between Hispanic children whose parents were interviewed in English and those whose parents were interviewed in Spanish on three measures.

The exploratory analysis revealed the need for multivariate statistical techniques that would simultaneously control for the demographic and administration variables in order to assess the Anglo-Hispanic and English-Spanish differences. As the dependent variables were in categorical form, logistical regression was used. Table 1 displays the nine maximum likelihood models for adults. The terms for all Hispanic respondents were significant in only one model: change in access to health care. Hispanic respondents were more likely to report that access to care had become more difficult than other respondents, after controlling for other significant demographic effects. The terms for Spanish-interviewed Hispanic respondents and for mode of administration were insignificant in all models.

Table 2 displays the maximum likelihood models for children. The terms for all Hispanic respondents were insignificant in all five models and significant for Spanish-interviewed Hispanic parents in three models. After controlling for household income and main wage earner education, Hispanic children whose parents were interviewed in Spanish are more likely to be in fair or poor health and less likely to be in good or excellent health than Anglo children or Hispanic children whose parents were interviewed in English. Hispanic children whose parents were interviewed in Spanish were less likely to have a usual source of care than Anglo children or Hispanic children whose parents were interviewed in English. Lastly, Hispanic children whose parents were interviewed in Spanish are less likely to have had a medical visit in the year prior to the survey than Anglo children or Hispanic children whose parents were interviewed in English. The term for mode of administration was insignificant in all models.

In seven of the adult models nonpoor respondents (those with household incomes greater than 185% of the federal poverty definition) had significantly better health status and access to care than the poor and near-poor respondents. In five of the adult models, poor respondents had significantly worse health status and access to care than the near-poor and nonpoor. The poor were also more likely than other respondents to have had one or more emergency room visits. Adults with less than a high school education had significantly worse health status and access to care (as measured by four models) than those who had finished high school or had post-high school education. In two of the children models, their living in a nonpoor household was significantly related to higher health status and access to care.

Discussion

For Hispanics in general, and particularly Hispanics in the southwestern United States, it is important to conduct interviews and analyze separately responses in Spanish for two reasons: to refine translingual and transcultural methodologies and to increase specificity through sampling in this most heterogeneous group. In addition, it presents the

opportunity for clinical and social studies of a group with high stress and for study of the long-term effects of political occupation. Each will be discussed.

Comparative validity of translated interview instruments for Spanish speakers in the United States has varied,[22–24] although it appears intact in other, more homogeneous Spanish speakers.[29] Cross-cultural comparisons of health status values have shown greater agreement at the more severe end of the dysfunction continuum and lesser agreement at the less severe end—in the same language.[30] Clearly, internal consistency requires further study. For example, our study would have been greatly enhanced on this dimension if physical examination of respondents had been feasible. At present, however, translated instruments are critical to adequately sample US Hispanics.

Specification of Hispanics in national research is critical because of the significant heterogeneity. There have been waves of immigrants secondary to political change or economic pain from the Caribbean and Central and South America and a steady flow from Mexico. In addition, Puerto Rico as a US territory, has an open-door policy with the United States. Not only does immigration come from diverse places, giving us Black Hispanics and White Hispanics, but the socioeconomic range is great and the political spectrum ranges from extreme right to extreme left. Given this diversity, generalization of Hispanics in national research can clearly be misleading.

Hispanics in the US Southwest have an even more complex history. Briefly, Spain occupied indigent peoples' territory from the Canary Islands in the North Atlantic Ocean, most of the Caribbean Islands, most of Central and South America, and North America—all of Mexico and the territory that is now Texas, California, Utah, Nevada, and parts of New Mexico, Arizona, Colorado, and Wyoming. Mexico overthrew Spain after 300 years, in 1821. In 1848, to end the Mexican War, Mexico agreed to cede the area now the above states to the United States in the Treaty of Guadalupe Hidalgo. The treaty guaranteed Mexicans' land rights, but these were not respected. Many southwestern Hispanics are descendants of area residents from the mid-1500s and earlier, of course—if the indigenous lineage is considered. In the meantime, there have been immigrants from Central and South America and the steady flow from Mexico.

Language of interview focuses on the earliest phase of the Hispano-US trajectory, which all southwestern Hispanics experience either by occupation or by immigration. Spanish monolingualism, in itself, is not a health risk factor but a practical indicator of important risk factors such as diminished education, poverty, and diminished access to care. This is seen as the trajectory progresses. Hispanic immigrants are learning English at the same rate as past generations of other immigrants[31] and are following the classic American pattern of integration into US society.[32] Studies reveal that they accept English as their language in the United States[33] and that the transition from Spanish begins in the immigrant generation. Ninety-five percent of their children speak English, and 50% of this second generation have lost Spanish-speaking ability, speaking English exclusively. These students do not fare much worse than all other students: in 1980, 39% of all Hispanic sophomores were enrolled in remedial courses in English, and 35% of all the nation's sophomores were enrolled in the same remedial classes.[32] While immigrants work at the lowest level jobs, their children move into skilled positions and their grandchildren into professional and managerial positions.[31] Examination of the factors for the 34% wage-offer differential between Mexican-descent men and other men attributes half of this inequality to education and only 2% to fluency in English.[33]

Our study has demonstrated the even greater increased vulnerability in inputs to health and in health care of exclusively Spanish speakers. Four interrelated findings bear elaboration: while reported health status of Spanish speakers and their children is low, the percentage without a usual source of care and without a recent ambulatory visit is significantly lower than the other groups'. We may conclude that the needed care is not obtained. Furthermore, the percentage with financial problems secondary to illness is significantly higher in this group. This, then, forms a vicious cycle: care is not obtained because of financial problems and lack of care causes financial problems. In addition to this hopelessness cycle is the added stress of recent "English only" laws. These are not only confusing, but perceived as menacing by Spanish speakers; often, this perception is accurate as to the roots of the laws. Monolingual Spanish speakers, including those refugees from Central America who have experienced torture and other human rights abuses, can provide insight into specific stressors and stress and into health in general.

The highly stressful early stage of the Hispano-US trajectory and its barriers have historically been overcome, albeit not achieving a status of other US citizens. Perhaps comparability of southwestern Hispanics' health status and other health-related measures is not realistic, given the groups' history. The long-term effects of political occupation, now being debated in other regions of the world, can be studied in southwestern US Hispanics.

Public health research of Hispanic populations can be more instrumental toward policy improvement if it increases its specificity with this heterogeneous group. Analysis of language of interview has a low cost and a high benefit toward this specification. □

Call for Abstracts on Nurse Practitioner Practice

The American Academy of Nurse Practitioners invites abstracts for its 1992 National Conference for Nurse Practitioners to be held in Washington, DC, June 11 to 14, 1992.

Completed or in-progress research papers concerning all facets of nurse practitioner practice are invited. Clinical and practice issues relevant to nurse practitioners are welcome. Full conference fee will be waived and presentation stipend will be provided. Please contact the Academy office at 512/442-4262 for details relating to submission of abstracts. The deadline for submissions is December 1, 1991.

Cancer Incidence in the Puerto Rican–Born Population of Long Island, New York

Anthony P. Polednak, PhD

ABSTRACT

Background. There are apparently no published data on cancer incidence in the Puerto Rican–born populations of the northeastern United States.

Methods. Standardized incidence ratios (SIRs) were calculated for 1980 through 1986 for the Puerto Rican–born population in Long Island (New York).

Results. Significantly reduced SIRs were found for males (SIR = 0.77) but not for females (SIR = 0.91), using expected numbers derived from incidence rates for all areas in the Surveillance, Epidemiology and End Results (SEER) Program (excluding Puerto Rico). Using incidence rates for Puerto Rico to obtain expected numbers, there was evidence for the retention of elevated SIRs for stomach cancer (both sexes) and for significantly elevated SIRs for lung cancer (both sexes), colon-rectum cancer (females), prostate cancer, and breast and uterine corpus cancer. Using rates for SEER areas, the SIRs for lung cancer approached 1.00, in contrast to other US Puerto Rican–born populations.

Conclusion. The data indicate the need for surveys on smoking and other health-related behaviors in the population studied and provide further evidence for heterogeneity in cancer patterns in US Puerto Rican–born populations. (*Am J Public Health.* 1991;81:1405–1407.)

Introduction

Migrant studies have contributed significantly to our understanding of changes in cancer rates that reflect environmental influences. Relative to the United States, cancer rates in Puerto Rico are reportedly higher for oral cavity, stomach, and cervix but lower for lung, breast, and corpus uteri.[1] Studies of cancer rates among the Puerto Rican–born population have been limited to mortality for the entire United States[2] and for selected areas such as New York City[3,4] and Illinois.[5] This report presents incidence data on a Puerto Rican–born population in the northeastern United States. According to analysis of data in the 1980 census microdata file,[6] 16.3% of the Puerto Rican–born population of Long Island (i.e., Nassau and Suffolk Counties in New York) was below the poverty level (Table 1); the figure for Puerto Rico was 62.4%.[7] Only 3.2% of the Long Island sample had resided in Puerto Rico in 1975, and only 18.8% did not speak English "well" or "very well" (Table 1).

TABLE 1—Puerto Rican–Born Population of Long Island (New York): 1980 Census

Characteristic	%
Total population	
Males	47.2[a]
Females	52.8[b]
Poverty level (%)	
<100	16.3
100–199	22.9
200+	58.5
Unknown	2.3
Education (age 25+ yrs.)	
High school graduate	43.9
Residence in 1975 (age 25+)[c]	
Same house	49.4
Same state	45.4
Puerto Rico	3.2
Other	2.0
Speaks English (age 25+)	
Only	9.3
Very well	43.7
Well	28.2
Not well	18.8

Note. Data calculated from 1980 census 5% microsample files.[6]
[a]n = 9440.
[b]n = 10 500.
[c]Based on a subsample.[6]

Methods

Data were obtained on all incident cancer cases (without personal identifiers) diagnosed among Puerto Rican–born residents of Long Island during 1980 through 1986 and reported to the population-based New York State Cancer Registry; 1986 was the latest year for which data were available at the time analyses were conducted. Cancers had been coded to the 9th Revision of the International Classification of Diseases.

Estimated numbers of Puerto Rican–born persons in the Nassau–Suffolk standard metropolitan statistical area[6] in 5-year age groups for each sex were multiplied by age- and sex-specific cancer incidence rates for all areas of the Surveillance, Epidemiology and End Results

TABLE 2—SIRs for Cancer in the Puerto Rican–Born Population of Long Island (New York) in 1980–1986, Using Rates from the SEER Program (excluding Puerto Rico) and from Puerto Rico: Males

Site	Observed No.	Using SEER Rates: Expected No.	Using SEER Rates: SIR (95% CI)	Using Puerto Rico Rates: Expected No.	Using Puerto Rico Rates: SIR (95% CI)
All sites	177	228.5	0.77 (0.66, 0.89)*	134.8	1.31 (1.13, 1.52)*
Oral	13	11.4	1.14 (0.61, 1.95)	15.9	0.82 (0.44, 1.40)
Stomach	12	6.7	1.79 (0.93, 3.13)	11.8	1.01 (0.52, 1.77)
Colon–rectum	16	31.1	0.51 (0.29, 0.83)*	12.7	1.26 (0.72, 2.04)
Lung	39	46.6	0.84 (0.60, 1.14)	12.9	3.02 (2.16, 4.11)*
Prostate	31	35.5	0.87 (0.59, 1.24)	18.7	1.66 (1.13, 2.37)*
Bladder	7	15.2	0.46 (0.18, 0.95)*	6.7	1.05 (0.42, 2.16)

Note. SIRs = standardized incidence ratios; SEER = Surveillance, Epidemiology and End Results. Data are shown only if the observed number, or the expected number (using SEER rates), was 10 or more. Adjustment was not made for estimated Puerto Rican-born cases among all cases with unknown place of birth in the Registry; such adjustment would increase slightly the SIRs reported in the tables, but use of 1980 Census data to estimate the population for 1980-86 has undoubtedly already resulted in some overestimation of the SIRs.
*$P < .05$.

TABLE 3—SIRs for Cancer in the Puerto Rican–Born Population of Long Island (New York) in 1980–1986, Using Rates from the SEER Program (excluding Puerto Rico) and from Puerto Rico: Females

Site	Observed No.	Using SEER Rates: Expected No.	Using SEER Rates: SIR (95% CI)	Using Puerto Rico Rates: Expected No.	Using Puerto Rico Rates: SIR (95% CI)
All sites	218	239.3	0.91 (0.79, 1.05)	136.0	1.60 (1.39, 1.84)*
Stomach	9	3.4	2.64 (1.21, 2.30)*	7.1	1.26 (0.58, 2.39)
Colon–rectum	29	26.7	1.09 (0.73, 1.57)	12.6	2.30 (1.54, 3.31)*
Lung	23	23.5	0.98 (0.62, 1.47)	5.4	4.25 (2.69, 6.38)*
Breast	62	79.0	0.78 (0.60, 1.01)	36.8	1.69 (1.31, 2.20)*
Cervix	13	9.5	1.37 (0.73, 2.34)	16.6	0.78 (0.41, 1.33)
Corpus	18	16.9	1.07 (0.63, 1.69)	7.9	2.29 (1.36, 3.62)*
Ovary	8	10.7	0.75 (0.32, 1.48)	5.5	1.45 (0.62, 2.86)

Note. SIRs = standardized incidence ratios; SEER = Surveillance, Epidemiology and End Results. Stomach cancer was included for comparison with data for males.

(SEER) Program of the National Cancer Institute, excluding Puerto Rico, for 1981 through 1985.[8] Expected numbers were also obtained by using age-, sex-, and site-specific cancer incidence rates for Puerto Rico (available for 1978 through 1982).[9] Age-adjusted incidence rates for Puerto Rico changed little between 1980 through 1984 and 1985 through 1987.[10] Statistical analysis involved calculation of 95% confidence intervals (CIs)[11] on standardized incidence ratios (SIRs).

Results

For males (Table 2) the SIR for all sites was significantly lower than 1.00 on the basis of SEER rates, but significantly greater than 1.00 on the basis of rates for Puerto Rico. The SIR for stomach cancer (using SEER rates) was 1.79, with no evidence for a change from numbers expected using rates for Puerto Rico. Using SEER rates, significantly reduced SIRs were evident for colon–rectum and bladder cancer. SIRs for prostate and lung cancer were slightly less than 1.00 using SEER rates but were significantly elevated on the basis of cancer rates for Puerto Rico.

For females (Table 3) the SIR for all sites was only slightly and insignificantly reduced using SEER rates, and significantly elevated on the basis of rates for Puerto Rico. The SIR for stomach cancer was even higher than that for males. In contrast to males, the SIR for colon–rectum cancer was greater than 1.00 using SEER rates and significantly elevated on the basis of rates for Puerto Rico. The SIR for lung cancer was nearly 1.00 (using SEER rates) and significantly elevated on the basis of rates for Puerto Rico. The SIR for breast cancer was slightly less than 1.00 using SEER rates and, along with uterine corpus cancer, significantly elevated on the basis of rates for Puerto Rico. The SIR for cervix cancer was slightly greater than 1.00 using SEER rates and less than 1.00 on the basis of rates for Puerto Rico.

Discussion

Potential inaccuracies in the SIRs are presumably due mainly to errors in estimating the population at risk and hence the expected numbers of cancers. Census data from 1980 should be more accurate for the 1980 through 1982 period than for 1980 through 1986, and observed cancers for 1980 through 1982 were compared with expected numbers based on incidence rates for SEER (excluding Puerto Rico) for 1978 through 1981.[12] For all cancers the SIR for 1980 through 1982 was significantly reduced for males (i.e., 0.72; 95% CI = .56, .92) but not for females (i.e., 0.80; 95% CI = .64, 1.00). SIRs for 1980 through 1982 based on at least 10 observed cases were 0.76 (15 observed vs 19.85 expected) for lung cancer and 0.92 (13 observed vs 14.16 expected) for prostate cancer in males, and 0.62 (19 observed vs 30.84 expected) for breast cancer and 1.22 (14 observed vs 11.45 expected) for colon–

rectum cancer in females, or similar to the SIRs in Tables 2 and 3.

For 1980 through 1986, males but not females had significantly reduced SIRs, on the basis of SEER cancer rates, for all cancers and for several sites. For females, both lung and reproductive system sites, with the exception of cervix, showed high SIRs calculated by using cancer rates for Puerto Rico. The findings are clearly consistent with other studies of migrants,[13] showing retention of high risks of stomach cancer (characteristic of the homeland) and a transition toward higher risks in the United States for certain other cancers such as those of the lung, prostate, and female reproductive organs.

The finding of an only slightly elevated SIR for cervical cancer (using SEER rates) may reflect the higher socioeconomic status (SES) of the Puerto Rican–born population in Long Island vs other areas where relatively high mortality for cervical cancer has been reported for Puerto Rican immigrants.[3–5] Selective migration, related to such characteristics as SES, is possible but difficult to document. The higher SES of the Puerto Rican–born population in Long Island (vs Puerto Rico) is most likely due to improvement in SES after migration from Puerto Rico, with subsequent movement to Long Island (mainly from New York City). Increasing SES may result in changes in environmental factors such as dietary and sexual–reproductive patterns, leading to increased risks of certain cancers (e.g., uterine corpus and breast) and a reduced risk of cervical cancer; the explanation of patterns for lung cancer may be more problematic.

Changes in smoking behavior among migrants are difficult to assess because data on smoking prevalence in Puerto Rico are limited to a 1965 through 1968 survey of men 45 through 64 years old,[14] and age at migration was unknown for the present group of migrants. In the 1982 through 1984 Hispanic Health and Nutrition Survey, Puerto Rican men and women had smoking rates higher than those of non-Hispanic Whites, but data have not been reported for the Puerto Rican–born subgroup.[14,15] The effect of increasing SES and/or acculturation on smoking habits and lung cancer rates in specific Hispanic subpopulations[14] requires further study, in view of the present findings on lung cancer in a higher income group of Puerto Rican–born US residents. □

Injuries in Working Populations: Black-White Differences

Diane K. Wagener, PhD, and Deborah W. Winn, PhD

ABSTRACT

Background. Although "accidents and adverse effects" mortality is higher among Blacks than Whites, annual injury rates reported in the National Health Interview Survey (NHIS) are lower among Blacks. We evaluated the influence of sociodemographic risk factors on injury rates among working adults.

Methods. NHIS data from 1983 through 1987 for currently working adults were used. Methods were developed to estimate standard errors using data from different sample frames and sample sizes.

Results. Working Blacks had fewer reported injuries requiring medical attention or restriction of usual activities than working Whites (22.0 vs 27.0 per 100 persons per year). The difference was pronounced among younger adults in both sexes and among both poor and nonpoor. However, age, sex, and income could not completely explain racial differentials. "At-work" injury rates (36% of all injury episodes) were similar for Blacks and Whites (9.2 vs 9.9 per 100 persons per year), except low-income Blacks and Blacks in service or blue-collar occupations had nonsignificantly smaller at-work injury rates.

Conclusions. Possible reporting biases could not be completely eliminated. However, available evidence does not rule out a true difference in injury rates by race, highlighting the complexity of understanding the etiology of injuries and, hence, developing public health programs to prevent injuries. (*Am J Public Health.* 1991;81:1418–1414)

Introduction

Injuries are a major cause of death among young adults and adults in their middle years.[1] More than one third of deaths among adults aged 20 to 34 years are due to accidents and adverse effects.[2] In contrast, 12% of deaths to adults aged 35 to 49 years and only 3% of deaths to adults aged 50 to 64 years are due to accidents and adverse effects. In addition to these deaths, each year there are 33.8 million nonfatal injuries to adults requiring medical attention or restriction in activity.[3,4] This report focuses on episodes of nonfatal injury.

In general, working adults have lower injury rates than other segments of the population.[3] However, injuries do have significant consequences for the working population. Injuries cause the loss of more working years of life than all forms of cancer and heart disease combined.[1] In 1980, injuries and poisonings were the leading category for medical costs among working age individuals in the United States.[5] Further, injury rates among workers are rising. From 1983 to 1989, the work-related injury rates reported by the Bureau of Labor Statistics' Annual Survey of Occupational Injuries and Illnesses steadily increased from 7.5 per 100 full-time workers to 8.2.[6,7] Likewise, yearly work loss due to injuries has increased (from 57.2 days per 100 workers to 74.2). These data are based on reports by employers that are subject to underreporting.[8]

Injuries occur in some population subgroups more than others.[9] Whites report more injuries than Blacks[10] but are far less likely to die of injuries than Blacks.[11–13] Injury rates are higher at younger ages.[3,4] To measure morbidity in working populations, regardless of its association with the workplace or employer-based reporting systems, and to examine the patterns of injuries in workers related to known important parameters such as race, we examined the incidence of injuries among US workers using data from the National Health Interview Survey (NHIS).

Methods

The NHIS is a continuing nationwide sample survey using personal household interviews conducted by the National Center for Health Statistics of the Centers for Disease Control.[4] Questionnaire information is collected on demographic and personal characteristics, illnesses, injuries, impairments, chronic conditions, health resource use, and other current health topics. The selection of households is based on a multistage probability sampling plan permitting national estimates for the noninstitutionalized civilian population of the United States. Over the years covered in this report, the response rate for the survey was between 95% and 98%.[4]

For this report, data from the survey years 1983 through 1987 were combined. Only currently employed adults 18 through 64 years of age were included. (Currently employed adults 65 years and over accounted for only 6952 out of a total of 216 528 interviews of all working

adults.) "Currently employed" included persons reporting that at any time during the 2-week period covered by the interview they either worked at or had a job or business. This included both paid and unpaid work. Those who were temporarily absent from a job or business were considered as currently employed if they expected to work as soon as the particular event causing the absence (e.g., vacation, strike, or illness) no longer existed.

An injury or injury condition was any condition classified according to the nature-of-injury codes 800 through 999 in the *International Classification of Diseases*, 9th version (ICD-9), modified for the NHIS.[14] An "episode of injury" was any accidental or nonaccidental violence causing an injury requiring medical attention or at least a half day of restricted activity, including bed days, work-loss days, or cut-down days. The recall period was 2 weeks prior to the interview. A person may have had more than one episode of injury during the recall period. Further, more than one type of injury could result from a single episode of injury. For the purposes of this report, "injury" will refer to injury episodes. The number of injury episodes during the 2-week recall period was multiplied by 26. Therefore, "injury rate" refers to the annual rate of episodes of injury.

For this report, data from 5 survey years were combined to enhance the stability of estimates for demographic subgroups. In 1985 the sampling frame for the NHIS was changed to include, among other features, oversampling in geographic areas with a high density of Blacks. Further, because of lack of funds, the numbers of households in the sample had to be reduced by one quarter in 1985 and by one half in 1986.

The NHIS is a clustered multistage probability sample; therefore, the Statistical Analysis System (SAS) procedure SESUDAAN[15] was used to compute rates, means, and their standard errors and to compute the effect of the complex survey design on the standard error, known as the "design effect".[16] Average annual rates for the 5-year period were estimated by pooling episodes and persons from all 5 years and, hence, both survey designs. The variance was, therefore, the weighted sum of the variance due to the 1983 through 1984 survey design period and the variance due to the latter 1985 through 1987 period. The variance for 1983 through 1984 could be calculated by using SESUDAAN. However, because sample sizes changed during 1985 through 1987, the variance for 1985 through 1987 could not be calculated in the usual manner and so was estimated using two approaches. The first approach assumed that the design effect was the same for both time periods and equal to the design effect for the sample collected in 1983 through 1984, $deff_c$. The variances for the 1985 through 1987 period were then estimated by multiplying the simple random sampling variance by $deff_c$. The second approach assumed that the coefficient of variation was constant over both time periods. Therefore, using the estimates for the rates in each time period and the variance for the first 2 years, the variance for the last 3 years could be estimated.

The design effects for injury-related parameters by demographic subgroups were generally between 0.7 and 1.4, which suggests only a moderate influence of the complex design on the standard errors. Standard errors presented here use the second—coefficient of variation—approach because (1) there was less than a 10% difference in the magnitudes of standard errors yielded by the two procedures, and (2) the coefficient of variation approach tended to yield larger (and hence more conservative) standard error estimates, especially for smaller subpopulations.

[a]Occupation classes include the following: White-collar: executive, administrative, and managerial; professional specialty; technicians and related support; sales; administrative support, including clerical. Blue-collar: precision production, craft and repair; machine operators, assemblers and inspectors; transportation and material moving; handlers, equipment cleaners, helpers, and laborers (except farm). Farm workers: farming, forestry, and fishing. Services: private household; protective service; service occupations, except protective and household.

Results

For the following analyses, the population included currently employed adults, aged 18 through 64 years. Table 1 gives the estimated population sizes and numbers of people interviewed by several demographic characteristics. Among the Black population, slightly more working adults were in the younger group (75%) or were women (50%).

Although the number of interviews was quite large (209 576), only 2016 working individuals reported an injury requiring medical attention or restricted activity in the previous 2 weeks, an annual weighted estimate of 27 382 000 injuries in the US working population. Table 2 gives the weighted numbers of injuries and rates

[a]Occupation classes include the following: White-collar: executive, administrative, and managerial; professional specialty; technicians and related support; sales; administrative support, including clerical. Blue-collar: precision production, craft and repair; machine operators, assemblers, and inspectors; transportation and material moving; handlers, equipment cleaners, helpers, and laborers (except farm). Farm workers: farming, forestry, and fishing. Services: private household; protective service; service occupations, except protective and household.

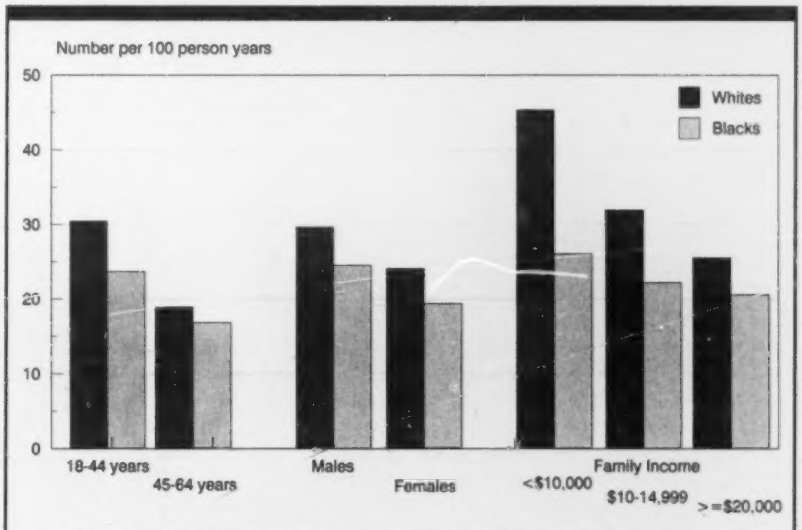

FIGURE 1—Injury rates among currently employed adults; race by age, sex, and income. (Source: National Center for Health Statistics, National Health Interview Survey, 1983–1987)

per 100 persons per year for the various demographic subpopulations listed in Table 1. For all characteristics, the rates were significantly different between pairs of subpopulations. (For race, "Whites" was used as the reference population; for income, "≥ $20,000"; for occupation, "white-collar"; and for education, "postgraduate.") Overall, approximately one in four working adults each year had an injury requiring medical attention or restricted activity. Approximately 89% of all injuries were medically attended (89% of injuries among Whites and 87% among Blacks), and 55% were associated with at least a half day of restricted activity (55% among Whites and 61% among Blacks). Injury rates were higher among the younger male, lower income, and White populations. Blue-collar and farm-related occupations had higher injury rates.

Figure 1 shows the injury rates for age, gender, and family income groups separately for Whites and for Blacks. In all comparisons except workers aged 45 through 64 years, working Blacks had fewer injuries per person per year.

Within age groups, differences between injury rates also were observed by gender. Among workers aged 45 through 64 years, there was no difference between men and women (18.7 per 100 persons per year vs 17.8), whereas, in the younger age group 18 to 44 years, men had a significantly higher reported injury rate (33.0) than women (25.3). When racial groups were compared separately for men and for women by age group, Black men in the younger age group had lower injury rates than White men (26.5 vs 33.9), but there was little difference by race among older men (18.8 vs 19.1). Among women, Blacks had lower rates in both age groups (20.9 vs 26.1 among women aged 18 to 44 years and 14.8 vs 18.4 among women aged 45 through 64 years).

Because the distribution of jobs differs between Whites and Blacks, Table 3 shows the injury rates by four major occupational classes and by race. There was no difference between Whites and Blacks among white-collar workers. There were too few Black workers in farm or farm-related occupations to reliably estimate the annual injury rate. Blacks had significantly lower injury rates among blue-collar workers and service workers. Within these occupational classes, there were racial differences in the types of jobs. Among service workers, 5% of Whites and 10% of Blacks worked in private households. Among the blue-collar workers, 12% of Whites and 19% of Blacks were handlers or equipment cleaners.

To determine whether the overall higher injury rates among blue-collar workers and service workers were found disproportionately among individuals with lower family incomes, the injury rates were further classified by family income (see Table 3). Low-income Blacks were more often working in service occupations (30%) than low-income Whites

(18%). There was little racial difference in the proportions employed in blue-collar occupations (33% of low-income Blacks and 36% of Whites). The injury rates among Blacks were smaller than among Whites for all occupation–income groups, except white-collar workers.

In the NHIS, injuries are grouped in four general classes: moving-motor-vehicles injuries, with traffic accidents as a subclass; accidents occurring while at work; accidents occurring in or adjacent to the home; and other accidents. These classes are not mutually exclusive. In the currently employed adult population, the distribution among classes of accidents was 12%, 36%, 25%, and 34%, respectively. Approximately 13% of the moving-motor-vehicle accidents occurred at work.

Because "at-work" injuries were the largest class of injuries and because all persons in this study population were currently employed, the at-work injury rates were calculated for the demographic subgroups (Table 4). In general, the at-work injury rate pattern was similar to all-injury rates. That is, rates were higher among the younger, male, and lower-income groups. However, in contrast to the all-injury rates, there was little difference between racial groups in at-work injury rates. Figure 2 shows these rates by racial groups for age, sex, and family income separately. Only among the low-income population was the Black at-work injury rate appreciably, though not significantly, lower than the White at-work injury rate. Approximately 93% of the at-work injuries were medically attended (93% among Whites and 94% among Blacks), and 54% were associated with at least a half day of restricted activity (54% among Whites and 59% among Blacks).

The rates for at-work injuries were calculated for the four major occupational groups by race (Figure 3). None of the comparisons by race were statistically significant. In general, the differences in rates of at-work injuries between racial groups were smaller than racial differences in rates of all injuries.

TABLE 3—Injury Rates in Major Occupation[a] Classes, Ages 18–64 years, by Race and Family Income: National Health Interview Survey, 1983–1987

Income and Race	White-Collar	Blue-Collar	Farm	Services
All income levels				
All races	21.82	36.20	32.75	25.58
Whites	21.84	37.95	30.24	28.27
Blacks	21.70	25.57	64.06[b]	14.77
Less than $20 000

Farm workers: farming, forestry, and fishing. Services: private household; protective service; service occupations, except protective and household.

Discussion

This study confirmed some previous findings in the injury epidemiology literature, but also generated some intriguing results. Injuries to US working adults are common, affecting a quarter of US workers every year. Reported injuries occur more frequently among the poor, among young men, and among the White population. Total reported-injury rates for working Whites exceeded those for working Blacks (27 vs 22 per 100 persons per year, respectively), but injuries occurring at work were not different between races (9.9 and 9.2, respectively).

In contrast to these findings for nonfatal injuries, injury death rates are about 18% higher in Blacks for injuries occurring at work[12,13] and for many specific causes of injury death regardless of whether the injury occurred at work.[11] Specific types

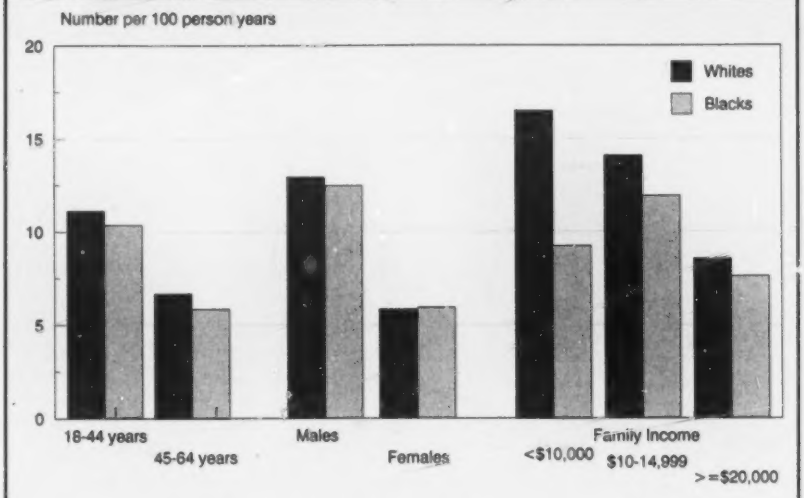

FIGURE 2—At-work injury rates among currently employed adults; race by age, sex, and income. (Source: National Center for Health Statistics, National Health Interview Survey, 1983–1987)

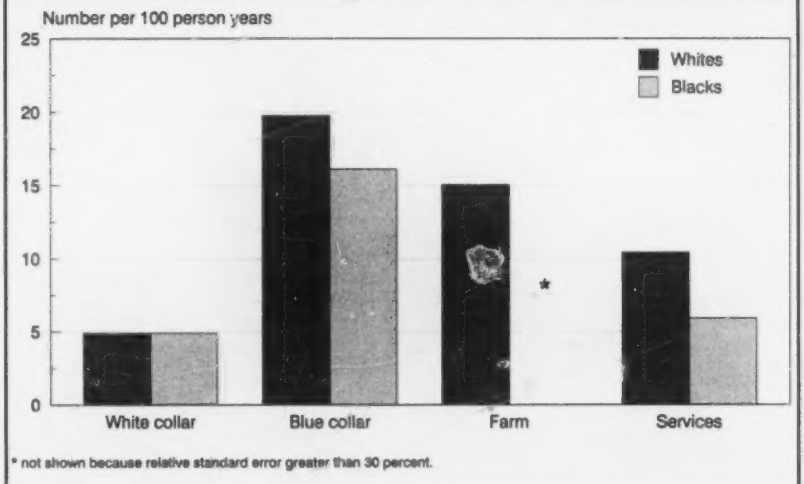

* not shown because relative standard error greater than 30 percent.

FIGURE 3—At-work injury rates among currently employed adults, by occupation and race. (Source: National Center for Health Statistics, National Health Interview Survey, 1983–1987)

of injuries (including nonfatal injuries) show different racial patterns. Hospital- and clinic-based studies have reported more Whites among motor vehicle injury or spinal cord injury victims,[17,18] and more non-Whites among penetrating injury or ocular trauma victims.[17,19] The demographic distributions of these patients, however, may reflect the populations served and not necessarily the rates of injuries in the population subgroups.

Major national surveillance systems that include nonfatal injury information, such as the Bureau of Labor Statistics' Annual Survey of Occupational Injuries and Illnesses and the Consumer Product Safety Commission's National Electronic Injury Surveillance System, either do not collect race or ethnicity data or do not routinely tabulate data by race. The NHIS is a source of national nonfatal injury information that provides both racial and ethnic information. This report and an analysis of data from the National Health Surveys from June 1959 through June 1961[9] (predecessors to the NHIS) show higher nonfatal injury rates for Whites, except for injuries occurring at work. In both analyses, the reported injury rates for Whites were about 23% higher than for Blacks (in this report) or for non-Whites (in the earlier report), although the rates have doubled over the time period. Reported injuries occurring at work have also doubled, but the racial difference has remained only about 5%. The authors of the earlier report hypothesized that racial differences in all-injury rates could be due to socioeconomic status, "culture" (including patterns of use of medical facilities), and nature of the work performed.[9] Some of these factors are evaluated in the present report.

Young (ages 18 to 44), working White men had the highest reported injury rates, significantly higher than their Black counterparts. Injury rates were highest among blue-collar workers. Among blue-collar and service workers, White rates exceeded those for Blacks, and this remained true when these occupational groups were further subdivided into income categories. Injuries occurring at work account for more than one third of all injuries occurring to working persons. The pattern of at-work injuries showed little of the racial differences observed for injuries in general, with the exception that, among the poor, at-work injury rates for Whites exceed those for Blacks.

In the NHIS, an event cannot be classified as an injury episode unless medical treatment was sought or there was at least one half day of restricted activity. The higher reported rate of injuries among Whites could be due to a truly higher rate, better access to medical care for Whites compared with Blacks, a greater opportunity for Whites to cut down on routine activities because of illness, or a higher probability that Whites will report an injury episode in this interview survey format.

A conclusion that Whites have higher rates of injuries than Blacks would be strengthened if it could be shown that other factors associated with race and the occurrence of injuries did not account for the findings. All of the factors we examined that were associated with greater injury reporting—lower income, lower education, and young age—were inversely associated with being White, suggesting that confounding could not account for the results.

Assessing access to medical care is complex. Other data from the NHIS[10] suggest that reported rates for Whites exceed those for Blacks for some health indicators that reflect contact with the medical care system: the incidence of acute

conditions (defined in part by contact with a medical care provider) and physician contacts per year. In this report, the percentage of episodes associated with medical care visits did not differ between Whites and Blacks, providing some indication that access to care was not responsible for our findings.

Family income[20] and health insurance coverage[21,22] are two important indicators of access to medical care. Blacks are more likely than Whites to be uninsured, potentially limiting access to medical care.[21,22] Insurance coverage data were unavailable for most of the survey years covered in this report, but income data were collected in all 5 survey years. Individuals with low family incomes might be expected to have less access to medical care and be less able to take time off from their activities, such as work. Therefore, it might be hypothesized that injury reporting would be lower in the poorer group even if their true rates were equal to or higher than those in other income groups. However, workers with family incomes of less than $20 000 had higher reported injury rates than higher income workers, and those with family incomes under $10 000 had injury rates higher still. Even among the poorest—where, regardless of race, income might severely influence taking time off or getting medical care—White rates exceeded rates for Blacks. Moreover, 88% of the injuries to low-income individuals were medically attended, nearly equal to the 90% rate for higher income individuals. Equal proportions of doctor visits in both income groups, however, does not necessarily indicate similarities in access to care. Data were not available to determine whether injuries considered severe enough to seek medical attention by one group were medically attended by individuals in another group.

Racial differences in the opportunities to cut down on routine activities or to stay in bed could explain the higher reported injury rates among Whites. Blacks may be more likely to have jobs in which staying away from work for reasons of illness carries greater financial consequences, although family income did not account for the racial differences reported here. Alternatively, family and nonwork responsibilities may make routine activity restriction difficult. A greater percentage of Blacks are in single-parent households[23] where opportunities for restricting activity may be limited.

If Whites have a higher probability of reporting health problems in an interview format, then this may account for the findings. Greater reporting by Whites probably would lead to Blacks having reported more severe conditions on average, but this could not be evaluated with these data. The National Center for Health Statistics is conducting a study of the reliability of reporting of health conditions using the NHIS interview and medical record data that may help evaluate racial differences in health event reporting.

Evaluation of potential biases is difficult. However, from the discussion above, it appears that the higher rate of injuries among Whites cannot be explained by sociodemographic correlates of race. Available indicators of access to care (e.g., percentage of injuries medically attended) and analyses by income level suggest that availability of health care did not account for the findings. No data were available to address whether racial differences in opportunities for activity restriction or willingness to report injuries had an impact on these results.

This study highlights the importance of analyzing separately injury patterns by the setting of the injury episode because the incidence of injuries at work did not show the same large differences by race for total injuries. Perhaps differences in access to care or opportunities for cutting down on routine activities generally are "leveled" by the workplace. Individuals working in the service occupations (e.g., personal service workers) are less likely to be provided health insurance packages[22] or may be offered less workplace health care, sick leave, or work-hour flexibility. This may explain the lower at-work injury rates among service workers compared with blue-collar workers. Further, our data show that Blacks are more likely to be in these occupations.

Despite their limitations, interviews with the victims of injuries would seem to offer the best opportunity for studying racial differences in nonfatal injury occurrence. These data are less dependent on access to care compared with reporting systems based on emergency room, compensation data, or physician records. However, this focused examination of racial differences in injury reporting suggests that methodological research be conducted on approaches to collect injury data via questionnaires. It will be important to reexamine existing definitions of injuries used in interview surveys to determine the extent to which these capture the injuries of greatest public health importance. Improved assessments of access to care and of barriers to reporting are needed in epidemiologic studies. Measuring severity of injuries should provide better insight into the public health aspects of injury and disability.

Injury epidemiology is an important public health concern, as evidenced by its inclusion as an emphasis area in the national health objectives for the years 1990 and 2000.[7,24] The workplace is an effective arena for health promotion programs. Therefore, understanding injury patterns within sociodemographic subgroups of the US working population is important. However, it is also important to have better information on injury patterns within sociodemographic subgroups of the entire US population. □

Health and Population Data for Developing Countries Available through USAID Project

The Demographic and Health Survey (DHS) Program, funded by the US Agency for International Development (USAID), is contributing unique data to the global database on population and health. To date, over 35 surveys have been conducted in developing countries, including Botswana, Kenya, Nigeria, Senegal, Zimbabwe, Indonesia, Sri Lanka, Peru, Bolivia, Ecuador, Egypt, and Morocco.

The DHS Program, administered by the Institute for Resource Development, Columbia, Md, began in 1984. The primary objectives of the program are to assist developing countries in building the technical skills and resources necessary for conducting demographic and health surveys and to provide developing nations with information for informed health and population policy choices. The data are gathered through a core questionnaire that is adapted to local needs and cultures.

The DHS core questionnaire has two parts: a household schedule for information on all household members and on household amenities and a woman's questionnaire for information on the woman and her children.

The DHS health data are used to estimate levels of neonatal, infant and child mortality; assess treatment practices for major childhood diseases; estimate coverage rates for maternity care and immunization; determine incidence of high-risk births; and assess regional variation in nutritional status.

The data can also be used to examine the relationships between various sociodemographic variables and health variables to better understand the health picture of developing countries.

The DHS survey data, which are maintained in a computerized archive, are available for 28 countries. Usually, several datasets are available for each country. These include women's data, household data, and service availability data.

In general, DHS datasets are available to researchers after the publication of the country survey report. For a few surveys, written permission is necessary from the in-country survey organization. The data files are accompanied by questionnaires, machine-readable descriptions and associated documentation. Currently, the cost of a DHS dataset is $200 ($50 for researchers in developing countries).

To order a DHS dataset, send a completed request form and description of your analysis project to the DHS Data Archive. Request forms are available from the archive. The address is DHS Data Archive, Institute for Resource Development, 8850 Sanford Boulevard, Columbia, MD 21045, USA. Tel: 301/290-2977; Telex: 87775; Fax: 301/290-2999.

Smoking, Social Support, and Hassles in an Urban African-American Community

Patrick S. Romano, MD, MPH, Joan Bloom, PhD, and S. Leonard Syme, PhD

ABSTRACT

Background. Despite public health efforts, the prevalence of smoking among African Americans remains high. The determinants of smoking behavior in this population must be elucidated so that interventions can be better targeted and more effective.

Methods. As part of a prospective community intervention trial to reduce cancer mortality, we conducted a random household survey of 1137 African-American adults in San Francisco and Oakland between November 1985 and July 1986. The survey instrument included questions about social network characteristics, instrumental and emotional aspects of social support, smoking behavior, and stressors.

Results. The overall prevalence of smoking (41.9%) was higher than that reported in national surveys. Logistic models revealed that persons reporting high levels of stress, represented by an abbreviated hassles index, were more likely to smoke than those reporting less stress. Women with poor social networks were more likely to smoke (odds ratio = 3.1) than women with optimal networks; however, this relationship did not hold among men. Indeed, men lacking emotional support from friends or family were less likely to smoke (odds ratio = 0.5) than men receiving such support. No interaction between social support and hassles was observed.

Conclusions. Stressful environments may contribute to high-risk smoking behavior among urban African Americans. (*Am J Public Health.* 1991;81:1415–1422)

Introduction

Educational efforts and innovative policies have reduced the prevalence of cigarette smoking among US adults from 41.7% in 1965[1] to 28.8% in 1987.[2] Despite this progress, 15.7% of deaths in 1984 could still be attributed to smoking.[3] African Americans suffer from a particularly severe burden of smoking-related disease. The age-adjusted smoking-attributable mortality rate among African Americans in 1984 was 143.2 per 100 000 persons compared with 119.0 among Whites.[3] The 1987 National Health Interview Survey found that 32.9% of African-American adults smoked compared with 28.5% of White adults; the proportion of ever smokers who had quit was far lower among African Americans (31.0% vs 45.8%).[2]

Much attention has therefore been directed to reducing the prevalence of smoking among African Americans.[4,5] Identification of factors that promote smoking in the African-American community is a prerequisite to developing effective interventions. Evidence from the 1987 General Social Survey suggests that stress may be such a factor.[6]

Stress and Smoking

Psychological stress can be defined as an "internal subjective state involving the perception of threat to one's well-being," while stressors are stimuli that provoke psychological stress in susceptible individuals.[7] Stressors have been shown to increase tobacco consumption among established smokers,[8] promote adolescent cigarette use,[9] predispose to smoking clinic failure,[10] and precipitate relapses among successful quitters.[11,12] Investigators have evaluated a variety of potential stressors, including anxiety-inducing tasks,[8] family turmoil,[9] job factors,[13] and major life events (e.g., unemployment, divorce).[6,10]

Lazarus and colleagues have recently argued that daily hassles may represent a better conceptualization of stress than traditional measures of major life events.[14] They define hassles as "the irritating, frustrating, distressing demands that to some degree characterize everyday transactions with the environment."[15] Hassles appear to predict many health outcomes, including psychological distress,[15] somatic symptoms,[16] respiratory illness episodes,[17] and arthritis-related disability.[18]

In a 12-month follow-up study of exsmokers who had participated in a smoking cessation program, the frequency and severity of hassles were significant predictors of late relapse in men, but not in women.[19] A similar evaluation of a work-site smoking cessation program found that the mean severity of hassles, but not the count, predicted relapse by 12 months.[20] Previous studies have not addressed the relationship between hassles and the prevalence of smoking in a community sample. Given the role of smoking as a psychological coping behavior,[7] we hypothesized that persons reporting numerous hassles

TABLE 1—Items from the Abbreviated Hassles Index (n = 1134)

Description	% of Respondents Reporting
Being out of work for a month or longer	47.9
Having a serious illness or accident	28.9[a]
Not having enough money for food, clothing, housing, or other necessities of life	31.0
Being concerned about getting credit	26.2
Having a problem with getting things repaired around the house	29.3
Having a check late or lost in the mail	21.1
Having something stolen or having the house or car broken into	24.9
Having a violent argument with a friend or relative	23.5
Having some other kind of trouble with family members	25.7
Being concerned about living in an unsafe area	36.8

[a]This item was deleted from the hassles index used in multivariate regressions to predict smoking behavior because it might represent a consequence rather than a cause of smoking.

would be more likely to smoke than those experiencing fewer stressors.

Social Support and Smoking

There is extensive epidemiologic evidence of a relationship between social support and diverse health outcomes.[21] Persons with high levels of social support have lower mortality rates,[22] have less coronary atherosclerosis,[23] and use less health care[24] than those with lower levels of support. Social support may exert these salutary effects partially by fostering changes in health-related behaviors, such as smoking. Indeed, successful quitters have higher levels of perceived support from their partners than smokers who never quit or relapse.[25] Having someone to talk to about one's problems predicted cessation in another recent study.[26] The prevalence of smoking is higher among separated or divorced persons than among those currently married or widowed,[2] even after controlling for other demographic characteristics.[27] We therefore hypothesized that persons with poor social support would be more likely to smoke than those with good support.

Buffering and the Stress–Support Interaction

The mechanism by which social support improves health outcomes has been a subject of intense debate.[28] Advocates of the buffering hypothesis argue that social support works by moderating the deleterious effect of stressful events and serving as "coping assistance."[29] Therefore, our final hypothesis was that any association between social support and smoking would be stronger among persons experiencing stressors than among those in low-stressor environments.

The present study was undertaken to assess the cross-sectional relationship between these social factors and smoking behavior in a large population-based sample of African-American adults in the San Francisco Bay area.

Methods

As part of a prospective controlled community intervention trial to reduce cancer mortality, a survey of African-American households in San Francisco and Oakland, Calif, was conducted between November 1985 and July 1986. Potential respondents were identified through two-stage probability sampling. In the first stage, 100 census blocks with at least 25% African-American population (according to the 1980 census) were randomly selected from each city. Specific households were then randomly selected from each block. Using the Kish procedure, interviewers randomly identified one respondent from each household with an African-American member aged 20 years or over.[30] A non-profit survey research organization hired, trained, and supervised field workers. Intensive efforts were made to interview persons who were not available during the initial visit. Follow-up telephone contacts with at least 10% of all respondents confirmed that the interviews took place and that the information obtained was accurate.

The survey instrument included questions about current health status, health behaviors, use of preventive services, sources of health information, knowledge and attitudes regarding cancer, social networks and stressors, and demographic characteristics. Smokers were defined in the usual manner[2] as individuals who currently smoked and had smoked at least 100 cigarettes since birth. Average daily consumption of 20 or more cigarettes was used as the cutoff to separate heavy smokers from light smokers. Demographic variables included age, gender, years of formal education, household income (recoded from an ordinal into a continuous variable), marital status, and employment. Respondents were asked to describe the impact of smoking on cancer risk (1 through 7 scale); those who indicated that it had no effect, a favorable effect, or an unknown effect were categorized as "unaware."

A four-item, health-specific locus of control scale was adapted from the work of Wallston et al.[31] This scale represents the mean of standardized Likert-type responses (coded 1 through 6) to four statements concerning self-control over health. A high score represents a strong belief in one's ability to avoid getting sick by taking care of oneself, to stay healthy by following "the advice of experts," and to control "the most important things that affect health."

A 10-item hassles index was created by abbreviating the original Kanner et al. list of 117 hassles.[15] Each item was chosen to represent a dimension that community residents involved in the project perceived to be especially relevant (Table 1). The second item ("having a serious illness or accident") was deleted from the scale because of concern that such events might be consequences rather than causes of smoking.[32] Scoring from zero to nine was based upon how many of the remaining hassles happened to the respondent or a person "most important" to him or her during the preceding three months. We did not employ an intensity scale because the frequency of hassles has superior predictive power.[15–17] In accord with Dohrenwend's recommendations,[32] we inquired whether these events occurred but did not ask for any judgment as to their significance.

The original Kanner et al. instrument was reported[17] to have a test–retest reliability of $r = 0.79$ with nine consecutive monthly administrations. Similar instruments developed by Weinberger et al.,[18] Wolf et al.,[33] and DeLongis et al.[34] have demonstrated 5- through 9-month median test–retest reliabilities of .72 to .77. Our abbreviated instrument had good internal consistency (Cronbach's $\alpha = .74$). We

validated the scale against demographic variables; the mean score was 2.5 for employed and 4.1 for unemployed respondents. Hassle scores were inversely related to family income ($r = -.19$, $P = .0001$).

Measures of social network characteristics can be categorized as either structural or functional. Structural features were assessed using Berkman and Syme's Social Network Index (SNI),[22] which measures four types of social ties: marital status, number of close friends, number of close relatives, and membership in formal groups. This index was modified slightly by adding two types of specified organizations (neighborhood and senior groups) and dropping a question on the frequency of contact with close friends or relatives. Scores range from one to four, where one represents those with the fewest relatives or friends and no history of church or group involvement. Functional features were assessed using Seeman and Syme's three-item Network Instrumental Support scale,[23] which measures whether respondents would "most likely" turn to friends or family for assistance with rides, borrowing "a small sum of money," or household repairs. Their four-item Network Emotional Support scale[23] was abbreviated to two items, only one of which had construct validity ("Who would you turn to for information or advice about a personal problem?"). This question, scored one for those who cited friends or family and zero for others, resembles the emotional support item used by Strogatz and James.[35]

The distribution of demographic characteristics was examined among smoking status categories: never smokers, ex-smokers, current light smokers, and current heavy smokers. Analysis of variance with two-tailed pairwise t tests and Bonferroni's correction for multiple comparisons was used to contrast the means of continuous variables. Chi-square analysis, with Yates' continuity correction for 2×2 tables, was performed on categorical variables. The Kruskal-Wallis procedure with two-tailed pairwise mean rank comparisons and Bonferroni's correction was applied to ordinal variables.

Multivariate logistic regression models were constructed to determine whether social support and hassles contributed to explaining smoking status after controlling for potential confounders. Heavy smokers and light smokers were aggregated because of their similar characteristics. In the absence of data about when or why respondents quit, both never smokers and ex-smokers were categorized as non-smokers in our primary analyses. Independent variables included age (with a quadratic term), gender, educational status (<12 years, 12 years, 13 through 15 years, and ≥16 years), household income (transformed to optimize fit), health-specific locus of control, and lack of awareness about the risk of smoking. These variables were selected on the basis of previous studies of smoking correlates.[2,36]

The abbreviated hassles index was then added to the basic model to determine the role of psychosocial stress, controlling for demographic and attitudinal characteristics. Social support variables were added next, with the reference group consisting of individuals with SNI = 4 (optimal) and Network Instrumental Support and emotional support scales greater than zero. To test the hypothesis that social support buffers the deleterious effects of stress, interaction terms between the hassles index and the three support measures were tested. All two-factor interactions involving demographics and social support were evaluated by forward selection and backward elimination procedures.[37] The significance level for entry and exit was $\alpha = .10$, with adjustment to ensure that terms derived from a single variable entered together. Hierarchical models were compared with the likelihood ratio test.

Finally, multivariate linear regression was used to determine factors associated with self-reported daily cigarette consumption among current smokers. Multicollinearities prohibited inclusion of interaction terms in this model. The PROC LOGIST and PROC REG programs in SAS were used for most analyses.[38] Odds ratios (ORs) and 95% confidence intervals (CIs) were calculated by exponentiating the logistic coefficient estimates. These ORs modestly overestimate the true risk ratios because the "rare disease" assumption underlying the OR is not satisfied.

Results

The total sample size was 1137, representing a response rate of 67.6% in Oakland and 69.1% in San Francisco. The age, gender, and income distributions of our sample closely resembled 1980 census data from the same neighborhoods. The San Francisco and Oakland samples were almost equal in size (569 and 568, respectively) and showed similar demographic characteristics. Therefore, they have been combined for all analyses.

Of the 1134 respondents who described their smoking habits, 36.0% never smoked, 22.1% had quit smoking, 26.8% were light smokers, and 15.1% were heavy smokers. Current smoking was more prevalent among women than among men (43.1% vs 40.1%), but female smokers were less likely than male smokers to consume 20 or more cigarettes daily.

Sociodemographic Characteristics by Smoking Status

Table 2 illustrates how the sociodemographic characteristics of current smokers differed from those of ex-smokers and never smokers. Ex-smokers were significantly older than current or never smokers. Ex-smokers were more than twice as likely to have graduated from college as heavy smokers (15.6% vs 7.1%). About 41% of heavy smokers and 36% of light smokers were separated or divorced, compared with only 20% of never smokers and 24% of ex-smokers. Current smokers reported lower household incomes than ex-smokers. Heavy smokers had a particularly high frequency of disability (15.4%); both light and heavy smokers were more likely to be unemployed than ex-smokers or never smokers. Current smokers had higher hassle scores than either ex-smokers or never smokers, whereas the latter two groups had higher SNI scores. More than 15% of heavy smokers denied a link between smoking and cancer, as compared with 4% of nonsmokers.

Intercorrelations Between Stress and Social Support Measures

Bivariate Pearson correlations between the social support and stress measures revealed only two significant associations. The hassles score was negatively related to the SNI ($r = -.10$, $P = .0009$), whereas Network Instrumental Support was positively related to emotional support ($r = .17$, $P = .0001$). The structural and functional measures of social support were not related to each other.

Demographic Predictors of Smoking Status

Table 3 shows the beta coefficients and ORs with 95% confidence limits for each variable in the basic logistic model, which included demographics, risk awareness, and locus of control. Lack of awareness of the smoking–cancer link was a strong correlate of current smoking, whereas health-specific locus of control

TABLE 2—Distribution of Selected Sociodemographic Characteristics by Smoking Status

Characteristics	Never Smokers (n = 406)	Ex-Smokers (n = 251)	Light Smokers (n = 304)	Heavy Smokers (n = 171)
Mean age, y (F = 15.14, $P < .0001$)	44.3[a]	48.7[b]	39.8	42.0
Gender ($\chi^2 = 31.72$, $P < .0001$), %				
Male	34.3	55.4	36.8	43.9
Education ($\chi^2 = 21.47$, $P = .01$), %				
Less than high school	26.9	27.2	20.2	30.2
High school graduate or equivalent	27.6	29.2	38.4	31.4
1–3 y college	33.8	28.0	31.8	31.4
4 or more y college	11.7	15.6	9.6	7.1
Marital status ($\chi^2 = 77.16$, $P < .0001$), %				
Married	36.2	49.0	25.3	28.1

Not in labor force	28.8	30.4	22.0	17.7
Locus of control, mean score (F = 1.21, $P = .30$)	0.03	0.04	−0.03	−0.05
Social Network Index, mean score (range 1–4, $\chi^2 = 33.67$, $P < .0001$)	2.47[d]	2.62[e]	2.29	2.07
Network Instrumental Support, mean score (range 0–3, $\chi^2 = 7.38$, $P = .06$)	1.51	1.34	1.51	1.55
Hassles Index, mean score (range 0–9, $\chi^2 = 22.81$, $P < .0001$)	2.37[f]	2.37[f]	2.95	3.28

[a]Different from ex-smokers ($P < .05$) and light smokers ($P < .01$).
[b]Different from never smokers ($P < .05$), light smokers ($P < .001$), and heavy smokers ($P < .01$).
[c]Different from light smokers ($P < .01$) and heavy smokers ($P < .05$).
[d]Different from heavy smokers ($P < .01$).
[e]Different from light smokers ($P < .05$) and heavy smokers ($P < .001$).
[f]Different from light smokers ($P < .05$) and heavy smokers ($P < .05$).

was marginally significant. The quadratic coefficient for age indicates that smoking prevalence peaked in middle age, with lower rates in young and elderly adults. College graduates were less likely to smoke than high school graduates, but no gender difference was noted. Current smoking was inversely related to household income.

Psychosocial Predictors of Smoking Status

When we added the abbreviated hassles index alone to this model, it significantly contributed to explaining smoking risk ($\chi^2 = 5.54$, $df = 1$, $P = .02$). We next added the five social support variables (SNI levels, Network Instrumental Support, and emotional support) and four interaction terms (Table 4). Only gender interactions with the SNI and emotional support scales met our entry criteria. Interaction terms between the hassles index and social support variables were not significant, either individually or as a group ($\chi^2 = 5.82$, $df = 5$, $P = .32$). The model in Table 4, which includes social network characteristics, was superior to that with only demographics and hassles ($\chi^2 = 30.68$, $df = 9$, $P = .0001$) in predicting smoking status.

A high frequency of hassles in the preceding 3 months was associated with increased likelihood of smoking for both sexes. With an OR of 1.07 per unit hassle, an individual with five hassles had 1.43 times the odds of smoking as a similar individual with no hassles. Strong social networks were associated with lower odds of smoking among women, but not among men. Conversely, men with inadequate emotional support were *less* likely to smoke than men with better emotional support. There was no relationship between this item and smoking among women. Instrumental support was independent of smoking.

Confirmatory Models

The robustness of these findings was tested in several ways. By using an income variable in regression equations, we lost 85 observations for which we had otherwise complete data. To examine the effect of this loss, we tested a model with employment status (employed, unemployed, not in labor force) in place of income. The prevalence of smoking was highest among those not in the labor force (OR = 1.48; CI = 1.03, 2.13), and the coefficients for psychosocial variables remained significant. Income and employment could not be included in the same model because of collinearity. We also tested a model in which social support variables were entered in continuous form. The findings were similar to those in Table 4, except that the interaction between gen-

der and SNI was weakened by implicitly forcing it to be uniform across SNI levels ($\chi^2 = 1.86$, $df = 1$, $P = .17$). A multiple linear regression model was used to test whether the association between psychosocial stress and smoking was driven by a cohort of light, relatively low-risk smokers. Hassle scores were positively related to self-reported cigarette consumption among current smokers, after adjusting for demographic characteristics ($t = 1.76$, $P = .08$). Social support variables did not improve the model ($F = 1.05$, $df = 5/407$, $P = .39$).

Since marital status is a component of the SNI, we examined whether the effect of that measure could be explained simply by a higher prevalence of smoking in separated and divorced adults. A logistic regression model that included SNI and marital status was significantly superior ($\chi^2 = 12.53$, $df = 6$, $P = .05$) to an otherwise identical model without SNI. Stratified analyses confirmed that lack of church involvement was related to smoking among married, separated/divorced, and widowed respondents. A small number of friends and nonmembership in community organizations were related to smoking among married persons, but not in other marital categories.

To explore whether psychosocial factors were related primarily to initiation or cessation of smoking, we performed a logistic analysis similar to the one in Table 4 but limited to ever smokers, with quitting as the dependent variable. Low SNI scores were associated with low odds of having quit smoking among women, but the hassles index was independent of smoking cessation ($\chi^2 = .06$, $df = 1$, $P = .81$). Age appeared to be the major confounder of the bivariate association between hassles and quitting (Table 2).

Discussion

The prevalence of smoking in this population-based probability sample of African-American adults was higher than that reported in studies using similar sampling techniques in the general population.[2] For example, the 1985 Current Population Survey found that 26% of Californians 20 years or older currently smoke.[39] The 1985 Behavioral Risk Factor Survey revealed current smoking rates of 26.3% and 24.9% in male and female Californians, respectively.[40] The gap between these rates and that observed by our group (41.9%) suggests that African Americans living in urban communities with large African-American populations are at especially high risk for smoking-related illness. Aggressive marketing by tobacco companies in these neighborhoods may be a contributing factor.[41]

Our study of African-American adults found that the prevalence of current smoking was highest among low-income, middle-aged individuals who never completed college. These findings are similar to those reported from the National Health Interview Survey[2] and a recent survey of Black insurance policyholders.[42] Our finding that individuals who lack awareness of the risks of smoking are more likely to smoke also corroborates previous work, particularly with adolescents.[43] This association may be explained in two ways: (1) People who are ignorant of the risks of smoking misperceive their vulnerability, or (2) nicotine addicts deny those risks to minimize cognitive dissonance.

Our measure of health-specific locus of control was only marginally related to smoking in multivariate models; however, individuals with a strong sense of control over health determinants tended to be less likely to smoke. Since the relationship between locus of control and smoking behavior has not been well studied, this finding should stimulate further investigation. The four-item scale we employed may not adequately represent the concept.

The independent association between hassles and current smoking has not previously been recognized. This effect was uniform by gender and did not change significantly after including social networks as a potential confounder. Among current smokers, hassled individuals tended to smoke more cigarettes daily than those relatively free of hassles. These findings support Lazarus' theory that the stresses of everyday life exert a cumulative impact on health.[14] Smoking may rep-

resent a coping behavior that mitigates the harmful psychological impact of a stressful environment. After controlling for other variables, hassles were not associated with ex-smoking among ever smokers. This finding suggests that hassles may influence smoking initiation more than cessation, but the cross-sectional nature of our data undercuts such an interpretation.

We observed that social support, as measured by the SNI, was inversely related to the likelihood of smoking only among women. This gender interaction may be a consequence of our measure or an inherent feature of how social support affects health behaviors. Male respondents may have exaggerated their social networks to appear well-adjusted to female interviewers. Men may be more responsive to unmeasured dimensions of social support, such as peer support directly related to quitting. Waldron and Lye[27] demonstrated that marital status is related to current smoking among both sexes, but the other three SNI components may be irrelevant for men. The potentially favorable effects of social networks for men may be outweighed by concomitant peer pressure to smoke. This hypothesis is supported by the observation that men who turn to close friends or relatives for help with personal problems are more likely to smoke than self-reliant men.

These data do not support the hypothesis that social support buffers the adverse impact of stressful events.[28] Instead, we found that social networks were associated with decreased smoking in women at all levels of hassles. Conversely, strong social support did not attenuate the detrimental effect of hassles. Social networks did not appear to operate by enhancing instrumental or emotional support for our female respondents.

Household interview surveys are susceptible to several sources of bias. Our sampling scheme excluded African-American families residing in predominantly non-Black census blocks. The further exclusion of institutionalized individuals and the homeless may limit the generalizability of our findings to the entire African-American community. Mis-

classification bias is always a concern in measuring sensitive behaviors, such as smoking. However, nondifferential misclassification of smokers as nonsmokers would not create artifactual associations between smoking and social factors.

Since our study design was cross-sectional, we cannot elucidate the chain of causation that links social support, stress, and smoking. Given present public attitudes toward tobacco, smokers who quit may experience improved social connections. Similarly, smokers may be more likely to suffer hassles than nonsmokers as a result of covert discrimination or physiological withdrawal symptoms. Recall bias may explain the associations if smokers reported more hassles or less social support in a post hoc effort to justify their unhealthy behavior. The likelihood of biased responses was minimized by separating questions about smoking from those about social factors and by disguising the research hypotheses. Finally, hassled persons and women with low SNI scores may possess other characteristics that are the actual determinants of smoking. The SNI could be a proxy for future orientation or interest in self-improvement; perceived hassles could reflect an underlying psychological vulnerability that predisposes to smoking.

The high prevalence of smoking noted among urban African Americans underscores the importance of smoking prevention and cessation activities focused on this population. Prospective studies with more detailed measures of support and stress are needed to clarify the direction of causation between psychosocial factors and smoking. The generalizability of our findings to other ethnic groups should also be evaluated. To the extent that smoking represents a behavioral response to stressful circumstances, prevention and cessation programs may achieve optimal success only by addressing larger community problems. As an interim measure, interventions to teach healthier coping behaviors may be efficacious. Interventions designed to improve social networks may have a particular role in smoking cessation programs for African-American women. □

Preventive Health Care for Children Works Better in Europe

Although they spend a smaller share of their gross national product on health care than does the United States, European countries achieve nearly complete participation of children in preventive health care and more favorable health outcomes for young children and adolescents. These are among the findings of a just-published report, *Preventive Health Care for Young Children: Findings from a 10-Country Study and Directions for United States Policy,* by Bret C. Williams, MD, MPH and C. Arden Miller, MD.

Supported by the William T. Grant Foundation and the US Maternal and Child Health Bureau, Williams and Miller looked at preventive health services for children from infancy through adolescence and at the social benefit programs that support children and families in Belgium, Denmark, France, the Federal Republic of Germany, Ireland, the Netherlands, Norway, Spain, Switzerland, and the United Kingdom. They found the following:

- Childhood mortality rates are higher in the United States than in Europe at all age levels, most markedly among children aged 1 to 4 years and adolescents aged 15 to 19 years.
- US immunization rates among preschool children lag behind European rates by 23% to 49%.
- US children are less likely to have a regular source of medical care than their European counterparts.
- US children are far more likely than children in Europe to experience injury-related deaths.

Williams and Miller found that the "truly remarkable aspect" of preventive health services in Europe is the nearly complete participation of children. Compliance with the full schedule of preventive health care visits generally exceeds 90% during the first year of life; completed immunization rates among young children are also generally above 90%. All health care for children in the study countries is financed under national systems that assure financial coverage of the entire population without means testing. Williams and Miller note that full availability of health care for children and social benefits programs for families came about in Europe only after earlier selective approaches failed.

Preventive Health Care for Young Children suggests that six attributes of European health systems are particularly worthy of US consideration:

1. Access to one or more provider systems that assure compliance with routine preventive services and linkage to more sophisticated care when necessary;
2. Separation of preventive services from the delivery of acute medical care, allowing the former to be rendered by less specialized personnel;
3. No means testing or payment required at the time of service delivery;
4. Linkage of families with children to benefit programs that alleviate poverty equitably across age groups;
5. Access of very young children to low-cost regulated programs for children of working parents;
6. A tracking system for children from birth through the age of 4 years to assure that young children and their families actively participate in health and social programs for which they are eligible.

Williams and Miller point out that European patterns of preventive health care and social supports are not strikingly different from the proposals of professional groups and public health agencies in the United States, including the majority of members of the National Commission on Children. They suggest that a national effort to improve preventive health care for children in the United States could build on what is being learned from US initiatives that include local prenatal health care programs, statewide tracking systems, and established, but underfunded, national efforts like WIC and Head Start.

Preventive Health Care for Young Children is a publication of the National Center for Clinical Infant Programs (NCCIP), a national nonprofit organization concerned with the healthy development of children and families during the first three years of life. In 1987, NCCIP published C. Arden Miller's monograph, *Maternal Health and Infant Survival,* an analysis of medical and social services to pregnant women, newborns, and their families in the same 10 European countries described in the new report.

Copies of *Preventive Health Care for Young Children* are available for $9.50 each; *Maternal Health and Infant Survival* is available for $7.50 per copy. Both reports may be ordered as a set for $15.00. Checks should be made payable to NCCIP and include shipping and handling charges of $3 for the first item ordered, $1 for each additional item, and 10% for orders of $60 or more. Send orders to the National Center for Clinical Infant Programs, PO Box 25494, Richmond, VA 23260-3494.

Cardiovascular Risk Factors among Asian Americans Living in Northern California

Arthur L. Klatsky, MD, and Mary Anne Armstrong, MA

ABSTRACT

Background. Recent substantial immigration has created large population subsets of Asian Americans in the United States. Available data about cardiovascular risk factors in these persons are sparse.

Methods. This study examined data among 13 031 persons self-classified as 5951 Chinese, 4211 Filipinos, 1703 Japanese, and 1166 other Asians. Covariates in regression analyses were age, smoking, alcohol, education, and marital status.

Results. Chinese men and women had the lowest adjusted mean body mass index. Filipino men and women had the highest prevalence of hypertension. There were no major differences in blood glucose levels. Total cholesterol levels were highest in Japanese men and women. Comparisons of US-born persons and those born in respective countries of origin showed no major cholesterol or glucose differences; more hypertension only in Chinese and other Asian men; higher body mass index in men, but not in women of most ethnicities; and a lower smoking prevalence in men, but a substantially higher one in women.

Conclusions. These data show important ethnic differences in risk factors among Asian Americans and indicate groups that should be targeted for public health efforts concerned with obesity (Asian-American men), hypertension (Filipino-American men and women), hypercholesteremia (all Asian Americans), and smoking cessation (Asian-American women). (*Am J Public Health.* 1991;81:1423–1428)

Introduction

Despite a marked acceleration of US immigration from Asia since the 1960s,[1,2] there are few reports concerning cardiovascular risk factors and disease incidence in Asian Americans. The available data[3–7] suggest more coronary artery disease among US-resident Japanese Americans (vs those resident in Japan), related to life-style changes. A study of elderly Chinese Americans[8] suggests risk factor profiles similar to those in China, with low risk of coronary artery disease and high risk of cerebrovascular episodes.[9,10] Two reports concerning blood pressure among Asian Americans in California[11,12] suggest that Filipinos are at greater risk; the authors of one[11] suggest that sociocultural factors are involved, but the authors of the other[12] raise the possibility of genetic influences. We have been given an opportunity to study cardiovascular risk factors among a substantial number of free-living Asian Americans and here present data concerning several of these traits.

Methods

Data were supplied by 13 031 Asian Americans who voluntarily took health examinations offered by a northern California prepaid health care program from the years 1978 through 1985. Sociodemographic and medical history data were obtained from a self-administered questionnaire that included the queries "What is your race?" and "Where were you born?" Previous descriptions have been published.[12,13] Sex and ethnic distributions are included in Table 1.

Examinees were asked to take no food or nutritious drink for at least 4 hours before their appointment time. Supine blood pressure was determined by a Roche Arteriosonde Blood Pressure Monitor, Model 1216. Blood chemistry tests were performed with a Technicon SMA 12-6 Multichannel Analyzer from January through May 1978; thereafter, an American Monitor ICDA Automated Chemistry Analyzer was used.

Adjusted means for body mass index, systolic blood pressure, diastolic blood pressure, total cholesterol, and glucose were determined by multiple regression analysis with the following covariables: age, body mass index (except when the dependent variable was body mass index), marital status, education, and alcohol use. Using the largest subgroup (Chinese) as the reference and with the same covariables in logistic regression models, odds ratios (ORs) were determined for high body mass index (≥ 24.4 kg/m^2 or 3.5 lb/in^2), hypertension ($\geq$ 140/90 mm Hg or on treatment), high cholesterol ($\geq$ 6.21 mmol/L or 240 mg/dL), high glucose ($\geq$ 6.11 mmol/L or 110 mgm/dL), current cigarette smoking, and current cigarette smoking of one pack per day or more. Similarly, but with birthplace as an additional covariable, the relations of various traits to each of these

[a]Or receiving treatment for hypertension.

end points were studied within each Asian-American ethnic subset using country of ethnic origin as the reference group. Thus, for Chinese Americans, those born in Hong Kong (n = 607), Taiwan (n = 245), Hawaii (n = 121), the continental United States (n = 2431), and other places (n = 438) were compared with those born in mainland China (n = 2109). For Japanese Americans, those born in Hawaii (n = 167) and the continental United States (n = 1174) were compared with those born in Japan (n = 331). For Filipino Americans, those born in the United States (n = 352) were compared with those born in the Philippines (n = 3815). The largest subsets of other Asian Americans were 295 persons born in Korea, 178 persons born in Vietnam, 252 persons born in India, 55 persons born in Thailand, and 58 persons born in Pakistan; we compared all 102 born in the United States with those born in all "other Asian" countries combined.

Results

Adiposity

Adjusted mean body mass index was lowest in Chinese men and women and highest in Filipino men and women (Tables 2 and 3); these means translated into higher prevalence (Table 1) and adjusted ORs (Table 4) of obesity for the Japanese, Filipino, and other Asian subsets vs the Chinese reference group. Birthplace in the continental United States was associated with increased ORs of obesity in men of all ethnic subsets (Table 5); this was also true for Chinese men born in Hawaii (OR vs birthplace in China = 2.4; 95% confidence interval [CI] = 1.3, 4.5) and for Japanese men born in Hawaii (OR vs birthplace in Japan = 3.2; 95% CI = 1.5, 6.6). Among women, only other Asians of US birthplace had similar increases in ORs of obesity (Table 5). Hawaiian-born Japanese women had an increased OR of obesity (OR vs those born in Japan = 2.4; 95% CI = 1.3, 4.4), but this was less true for Chinese women born in Hawaii (OR vs birthplace in China = 1.5, 95% CI = 0.8, 2.9). Chinese men and women born in Hong Kong or Taiwan had no substantially different ORs of obesity when compared with their counterparts born in China (data not shown).

Among men and women, age and currently married status were positively related to obesity. Educational status and alcohol consumption were not related to this trait among men but showed inverse relations to obesity in women.

Hypertension

The increased hypertension risk of Filipino Americans has been described.[12] Only in Chinese men was continental US birthplace associated with more hypertension (Table 5). Chinese and Japanese men and women born in Hawaii did not have increased risk of hypertension compared with their counterparts born in China, nor did Chinese men born in Hong Kong or Taiwan, or Chinese women born in Hong Kong. Chinese women born in Hong Kong had *less* risk of hypertension (OR vs China-born = 0.3; 95% CI = 0.1, 0.8).

Cholesterol

In each sex, the adjusted means were lowest in other Asians and higher in Japanese men and women than in other ethnic groups (except for small differences between Japanese and Filipino men) (Tables 2 and 3). Compared with the Chinese reference group, only Japanese men and women had increased ORs for high cholesterol (Table 4). Birthplace in the continental United States (Table 5) or in Hawaii (data not shown) vs birthplace in country of origin carried no substantially different ORs for high cholesterol. The only birthplace subset with such a difference was the Chinese women born in Hong Kong (OR vs birthplace in China = 1.5, 95% CI = 1.1, 2.3).

For comparison, unadjusted mean total serum cholesterol was 5.49 mmol/L (212.4 mg/dL) among Black persons (n = 32 890), 5.57 mmol/L (215.4 mg/dL) among White persons (n = 73 920), and

TABLE 2—Adjusted Mean Risk Factors among Asian-American Men

Risk Factor	Ethnicity (Adjusted mean ± SE)				Pairs for Which $P < .01$
	Chinese	Filipino	Japanese	Other Asian	
Body mass index (kg/m²) (Quetelet's)	22.9 ± 0.1	23.9 ± 0.1	23.7 ± 0.1	23.6 ± 0.1	C vs all
Systolic blood pressure (mm Hg)	122.2 ± 0.3	124.4 ± 0.4	121.3 ± 0.6	120.3 ± 0.7	F vs all
Diastolic blood pressure (mm Hg)	75.5 ± 0.2	75.5 ± 0.2	73.9 ± 0.4	74.0 ± 0.4	F vs J, O
Total cholesterol (mmol/L)	5.59 ± 0.02	5.67 ± 0.03	5.72 ± 0.04	5.52 ± 0.05	F vs O
Glucose (mmol/L)	5.45 ± 0.03	5.54 ± 0.03	5.54 ± 0.05	5.54 ± 0.06	0

Note. Each risk factor was considered separately as a dependent variable in a linear regression analysis that produced means for each ethnic group, adjusted for age, marital status, education, alcohol intake, and body mass index (except when body mass index was the dependent variable). C = Chinese; F = Filipino; J = Japanese; O = other Asian.

TABLE 3—Adjusted Mean Risk Factors among Asian-American Women

Risk Factor	Ethnicity (adjusted mean ± SE)				Pairs for Which $P < .01$
	Chinese	Filipino	Japanese	Other Asian	
Body mass index (kg/m²) (Quetelet's)	21.2 ± 0.1	22.6 ± 0.1	21.6 ± 0.1	22.2 ± 0.1	C vs all
Systolic blood pressure (mm Hg)	116.3 ± 0.3	119.2 ± 0.3	115.7 ± 0.5	115.9 ± 0.6	F vs all
Diastolic blood pressure (mm Hg)	71.7 ± 0.2	72.9 ± 0.2	70.3 ± 0.3	70.8 ± 0.4	F vs all
Total cholesterol (mmol/L)	5.33 ± 0.02	5.35 ± 0.02	5.52 ± 0.03	5.26 ± 0.04	J vs all
Glucose (mmol/L)	5.22 ± 0.02	5.24 ± 0.02	5.26 ± 0.04	5.28 ± 0.05	0

Note. Each risk factor was considered separately as a dependent variable in a linear regression analysis that produced means for each ethnic group, adjusted for age, marital status, education, alcohol intake, and body mass index (except when body mass index was the dependent variable). C = Chinese; F = Filipino; J = Japanese; O = other Asian.

5.47 mmol/L (211.6 mg/dL) among all Asian-American persons combined.

Glucose

Study of adjusted mean blood glucose levels showed no major differences in any of the comparisons.

Smoking

Chinese men and women were least likely to smoke any amount or to smoke heavily (Tables 1 and 4). Among women, the Japanese were most likely to be smokers; among men (other than Chinese), the differences in smoking were smaller. Generally, men born in the United States were less likely to smoke than their counterparts born in Asia, although there was little difference with respect to heavier smoking (Table 5). Chinese men born in Hawaii, Hong Kong, or Taiwan were slightly less likely to smoke at all or to smoke heavily compared with Chinese men born in China (data not shown); Japanese men born in Hawaii were slightly less likely to smoke at all and substantially less likely to smoke one pack or more per day (OR = 0.3, 95% CI = 0.1, 0.9) than their counterparts born in Japan.

With the exception of Japanese women, women born in the United States were more likely to smoke and had substantially increased adjusted ORs for heavier smoking (Table 5). Chinese women born in Hawaii (but not those born in Hong Kong or Taiwan) were also more likely to smoke (OR vs Chinese birthplace = 3.6, 95% CI = 1.7, 5.5), or to smoke one pack or more per day (OR = 9.8, 95% CI = 2.1, 46.0). Hawaiian-born Japanese women, like those born in the continental United States, were, compared with their Japan-born counterparts, less likely to smoke any amount (OR = 0.5, 95% CI = 0.2, 0.98) or to smoke one pack or more per day (OR = 0.5, 95% CI = 0.1, 2.3).

Among both sexes, alcohol drinking was strongly related and college graduation inversely related to smoking. Other traits related to smoking among men were age (weak negative), body mass index (weak negative), and married status (strong positive); among women, age (weak negative) and marital status (weak negative) were related to smoking.

Discussion

There is a consensus that coronary artery disease is related substantially to all of the risk factors discussed in this article and that cerebrovascular disease is related to several. Cigarette smoking is presumably not primarily determined genetically, whereas the other risk factors studied are determined by both genetic and life-style factors. The presumption that US-born persons of each Asian-American ethnic

TABLE 4—Odds Ratios for Risk Factors among Asian-American Ethnic Groups

group are more likely to practice US lifestyle habits will be the basis for further discussion.

If the observed smoking differences represent cultural influences, ethnic group differences in smoking behavior probably reflect differences in the respective countries of origin. Asian-American men born in the United States are apparently subject to the same antismoking influences that have resulted in a substantial reduction in smoking among US men of other ethnicities.[14] In a study of ethnic Japanese men,[4,15] a much larger proportions of men in Japan than in Hawaii or California were light smokers, but the proportions of heavier smokers were similar in Japan and California (higher in Hawaii). We found both lighter and heavier smoking to be less prevalent in Japanese men born in the continental United States and Hawaii. Although the two studies used different methodologies, the data suggest that acculturation has resulted in less smoking among Japanese-American men over the 10 to 15 years between the dates of collection of data. We know of no comparable data about smoking that compare US-born and Asia-born persons of other ethnicities.

Why, then, do US-born Asian-American women (except the Japanese) exhibit so much more smoking than their Asia-born counterparts? Some of this can probably be explained by the fact that, among the Asia-born people, the women were much less likely to smoke than the men (Japanese women again excepted). This reflects the situation in the countries of origin.[16,17] It is plausible to hypothesize that the more liberal attitude of American society toward behavior or women tends to equalize this gender disparity in smoking, especially in persons of high educational attainment. Asian-American women born in the United States, under less intense specific social pressures against women not to smoke, apparently take up the habit. In this respect, Asian Americans become similar to other US ethnic groups; among young US White and Black persons, smoking is now almost equally prevalent in the sexes.[14] The Japanese Americans in our study were older and were the only ethnic group with a preponderance of US-born persons; these factors probably account for the smaller gender difference in smoking behavior. Whatever the explanation, these data about smoking suggest an area of major public health concern. The attributable risk of smoking to coronary heart disease is high in young women.[18] By its nature, smoking is the coronary disease risk factor most amenable to complete control. Thus, smoking cessation programs should be targeted toward Asian-American women.

The finding of greater risk of adiposity among US-born and Hawaii-born persons (vs counterparts born in Asian countries) was expected, both on the basis of prior data in Japanese men[4,15] and presumed dietary habits. We did not, how-

ever, expect greater adiposity in US-born persons to be limited to men. College education and use of alcoholic beverages were inversely related to adiposity in women but not men in this study. These relations support the argument that acculturation operates in the direction of more emphasis on slimness and fitness in the United States among women but not among men. We have no other data to support this speculation. We do not know whether the interethnic differences we found in the United States reflect similar differences in Asian populations, but suspect they do. Our findings confirm the need to control for body mass index in studies comparing cardiovascular risk factors among ethnic groups.

The only two relevant studies known to us[11,12] agree that Filipino Americans are at greater risk of hypertension than other Asian-American groups. Whatever the explanation, the data have potential implications for research about the pathogenesis of hypertension,[12] as well as pointing to an area for public health efforts.

There are almost no previously reported data concerning cholesterol levels in Asian-American groups. Mean total cholesterol and low-density lipoprotein (LDL) cholesterol levels are lower in Asian countries[19–26] than in Western societies. Higher mean cholesterol levels among ethnic Japanese men living in Hawaii and California (vs those living in Japan) are believed to be due to the higher proportion of fat in the Western diet.[27] We did not find that, independent of body mass index differences, US-born persons of each ethnicity had higher cholesterol levels than their counterparts born in the countries of origin, suggesting either that immigrants from Asia rapidly adopt a high-fat diet or that their progeny maintain similar dietary habits. In support of the former explanation are the similarities of mean total cholesterol levels in US Blacks, Whites, and Asians and scattered reports of rapidly rising fat intake and cholesterol levels in several Asian countries.[22–29]

In this young study population with a majority of women, it will be several more years before the study will have the power to discern possible differences in major cardiovascular disease outcomes. On the basis of the risk factor data herein described. Chinese Americans should fare the best and Filipino Americans and Japanese Americans should fare the worst. For the present, these data can be of use to workers in preventive cardiology. Special efforts should be focused on weight control in Asian-American men, on cigarette smoking among Asian-American women, on diagnosis and treatment of hypertension among Filipino-American men and women, and on control of hypercholesteremia in all Asian Americans. □

Acknowledgments

This research was presented in part on November 14, 1988, at the American Heart Association 42nd Annual Scientific Session, Washington, DC; on October 1, 1990, at the 118th Annual Meeting of the American Public Health Association in New York, NY; and on November 12, 1990, at the 44th Annual Scientific Session of the American Heart Association in Dallas, TX. Data concerning blood pressure in Asian Americans have been published.

The authors thank Harald Kipp for computer programming, Cynthia Landy and Rita Coston for data collection, and Lyn Wender for assistance in preparation of the manuscript.

This research was supported by the Alcoholic Beverage Medical Research Foundation Inc, Baltimore, Maryland. The study protocol was approved by the Kaiser Permanente Medical Care Program, Northern California Region, Institutional Review Board.

Physician Program Cut Infant Death Rate by 45%

Physicians serving poor Miami neighborhoods under a controversial national program cut the infant death rate by 45%, according to a School of Medicine study published in the September issue of *Obstetrics and Gynecology.*

The University of Miami research study is the first documentation of the effectiveness of the National Health Service Corps, a federal program that provides financial assistance to medical students in exchange for a commitment to practice for 1 to 4 years in medically needy communities. The Corps was virtually dismantled by the Reagan administration but has since been partially restored by President Bush in response to pressure from the poor and from physicians.

According to the study, the Corps program saved the lives of at least 320 infants in Miami from 1987 to 1989. Three University of Miami physicians, Hoa Nguyen, Mary Jo O'Sullivan, and Arthur Fournier, examined the impact of placing eight Corps pediatricians and seven obstetricians with four public health clinics: Borinquen Health Care Center in Little Havana, Family Health Center in Liberty City, Community Health of South Dade, and Stanley Myers Community Health Center in Miami Beach.

Before the arrival of Corps physicians, perinatal mortality rates among the poor in Miami varied from 29 to 36 per 1000 live births—about twice the national average of 15.6%. Poor maternal nutrition, financial problems, lack of transportation to clinics, substance abuse and unawareness of pregnancy were cited as contributing factors to the high infant death rate.

Within a year, the mortality rate in the neighborhoods with Corps physicians had fallen to 16 deaths per 1000 live births. In 1988 the rate remained 16 per 1000 and in 1989 it dropped to 13 per 1000, which is better than the national average. There was no significant change in death rates for three other Miami community health centers without Corps obstetricians and pediatricians.

"The Corps physicians were able to follow patients more closely, checking on nutrition and pregnancy complications like diabetes or hypertension. Corps obstetricians were able to supervise deliveries, and pediatricians monitored high-risk babies," said Dr. Arthur Fournier, associate dean for Community Health Affairs at the University of Miami School of Medicine, who served as a Corps physician in rural Onley, Va in 1976 to 1977.

Since the study was conducted, the 15 Corps physicians completed their obligations and left the Miami centers.

"Reagan felt the program was a failure because it didn't keep physicians in the underserved communities after their commitments expired," said Fournier. "But our study demonstrated that for the time they were there, they made a significant impact."

The National Health Service Corps began recruiting volunteers in 1972 to serve in medically needy communities. Scholarship awards peaked during the Carter presidency. But because students did not serve until after they completed their residency training programs, the number of active Corps physicians did not hit its highest point until 1986, when 1400 served. Awards dwindled to a low of 50 in 1988 before rebounding last year. As of May 1991 there are 131 scholarship holders, according to Lynn Trible, public affairs specialist for the Health Resources and Services Administration in Washington, DC. Altogether, 13 804 medical students have gone through the Corps program.

Ethnic Populations in Public Mental Health: Services Choice and Level of Use

Teh-wei Hu, PhD, Lonnie R. Snowden, PhD, Jeanette M. Jerrell, PhD, and Tuan D. Nguyen, PhD

ABSTRACT

Background. Barriers to access and use of mental health care by Asians, Blacks, and Hispanic Americans have been a source of concern for many years. Limitations in our knowledge base persist regarding patterns of use in public sector programs of certain services. Using a sample of almost 27 000 persons, this study examined access and level of use by ethnic minority groups of emergency services, inpatient care, individual outpatient visit, and case management.

Methods. Data from the management information systems of San Francisco and Santa Clara counties were analyzed for fiscal year 1987/1988. Multivariate models were evaluated at two stages, reflecting whether or not a service had been used, and if used, the level of use.

Results. Asians and Hispanics used less emergency and inpatient but more outpatient care than did Whites; Blacks used more emergency and less outpatient care.

Conclusions. Ethnicity continues to play a role in understanding the utilization of mental health services. Regarding emergency and inpatient care, Asian and Hispanic patterns of use appear relatively favorable, whereas the patterns of Blacks continue to be problematic. (*Am J Public Health.* 1991;81:1429–1434)

Introduction

Providing adequate mental health services to the US population has been a national policy for over 20 years. Achieving this objective requires an understanding of factors that affect utilization of mental health services, especially for minority populations. That these populations encounter unusual problems in obtaining mental health services has been acknowledged by the President's Commission on Mental Health.[1] The Commission's 1978 report targeted Asian, Black, and Hispanic Americans for expanded research on the delivery and financing of mental health services and on factors affecting their utilization. More than 10 years later, information on mental health service delivery to ethnic and racial minority populations remains limited. The goal of this article is to provide information on minority utilization of public mental health services that will be useful for planning and policy evaluation.

Previous research on minority utilization of mental health services has focused on several aspects of the problem. Increasingly rigorous studies on community-based samples have tended to emphasize treatment seeking.[2–5] Community-based studies that have gone beyond treatment seeking and looked at patterns of use among those utilizing services have restricted themselves to minority groups in the aggregate[6] or to a single minority group.[7] Also, few studies have focused completely on the public sector.[8]

Large-scale studies of minority utilization of public sector mental health services have been conducted in Seattle, Wash, and in Los Angeles. Sue[9] found that Black, Asian, Native, and Hispanic Americans in Los Angeles County had fewer contacts than Whites with mental health facilities and were more likely not to return after an initial session. In a follow-up of this same county's mental health system 10 years later,[10] O'Sullivan and colleagues discovered major changes. Blacks still failed to return after a single session at a rate higher than Whites, and Asian Americans continued on average to attend fewer treatment sessions after the initial contact. Otherwise, ethnic differences had disappeared. Armstrong and colleagues investigated differences between Blacks and Whites attending a single community mental health center in Seattle.[11] Despite roughly equivalent sociodemographic profiles and similar diagnoses for Blacks and Whites, differences in utilization were found. Whites were more likely than Blacks to have participated in brief therapy, day treatment, activity therapy, and group therapy, as well as in a psychiatric day treatment program and in transitional care. Yamamoto and Silva examined out-

patient services delivered by the Los Angeles County Mental Health Department.[12] Hispanics received fewer mental health services than Blacks and both groups received fewer services than Whites.

Previous studies of ethnic differences in the use of public mental health systems have several limitations. In particular, few have controlled for group-related differences in diagnosis and level of functioning. Parameters have been estimated without regard for the limitations of dependent variables, including the highly skewed distributions that characterize indicators of mental health service utilization. The problem of utilization has rarely been recognized as consisting of two components: initial use vs. nonuse of a service by clients in the system and level of use among clients with initial use. This article focuses on patterns of public mental health service utilization among Asian, Black, and Hispanic Americans in California's San Francisco Bay area (San Francisco City and County and Santa Clara County). The White population was included in the study as a comparison group for determining distinctive patterns of utilization, after controlling for other potential demographic and clinical differences among the ethnic and racial groups.

Because not every individual used all types of mental health services, this article first studies the probability of using a particular mental health service, and then looks at the amount of use once an individual is engaged in the service. This estimation approach will enable us to address the issue of accessibility of a particular service for a particular ethnic or racial group. We have chosen four major mental health services to study: emergency, inpatient, case management, and individual outpatient services. It is hypothesized that individuals from ethnic and racial minority groups have different probabilities of using these services because of both their ethnic backgrounds and the service policies of the providers.

Methods

Data

This study used two data sources: San Francisco City and County and Santa Clara County for the fiscal year July 1987 to June 1988. Both areas used the Mental Health Billing Information System, which is operated under an interactive data entry and retrieval system. These data are received by clinicians on an episodic basis. The data on amount of use should be accurate because this information is used for billing purposes. However, the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) diagnosis code and the Global Assessment Scale (GAS) may be subject to the clinician's judgment or billing requirements. The reliability and validity of these codings have been reviewed by clinicians at the University of California at San Francisco and reviewed internally by the director of information systems in both counties. The DSM-III[13] ratings were found to be more accurate than the GAS ratings because DSM is the criterion for reimbursements.

Research files were created from raw data files with multiple checks for completeness and accuracy. Both counties have high percentages of ethnic minority populations. Santa Clara has a high proportion of Hispanics, while San Francisco has a high proportion of Asian Americans. Combining the two counties increases the sample size and provides more precision in making empirical estimates. The study excluded persons less than 18 years old and individuals whose treatment was mandated or in any way connected with the criminal justice system. After deleting these observations, the study included 26 708 individuals that used different types of public mental health services. Fourteen percent (n = 3825) are Asian, 15% (n = 3895) Black, 14% (n = 3842) Hispanic, and 57% (n = 15146) White.

Sample Description

Table 1 presents the sociodemographic and mental health characteristics of the sample by ethnicity or race. The sample contains relatively high percentages of Asian and Hispanic females. Asians in the sample had lower educational levels than the other groups. Possibly many Asian immigrants who came to the two counties were older and had lacked educational opportunities in their country of origin. The Asian population

had the highest percentage of non-English-speaking users, followed by the Hispanic group.

DSM-III classification[13] and GAS scores are recorded by clinicians during the client's first visit in the 1987–1988 fiscal year. They provide information on initial psychological status. GAS scores ranged from 0 to 99, with higher scores indicating better functional status. The mean GAS score was around 45 and scores were not statistically different among populations. Schizophrenia, affective disorder, and adjustment reactions, the three most common classifications, represent about two thirds of all diagnoses. Asians and Hispanics were more often diagnosed as having adjustment difficulties, perhaps reflecting their immigrant and refugee status, and Blacks were diagnosed more often as schizophrenic. This finding has been reported by Jones and Gray.[14]

Public mental health services include emergency, inpatient, skilled nursing, residential, case management, individual outpatient, medication, and group outpatient services. Of the four services addressed in this article, emergency service is often considered the least desirable type of mental health service; inpatient is the most expensive service; case management is the most important form of community mental health service; and individual outpatient is the most used service.

Table 2 provides information on the percentage of use for these services among the racial and ethnic populations studied. The data show that a higher percentage of Hispanics and Whites (4%) than Asians and Blacks (2%) used inpatient services. A higher percentage of Blacks than other groups used case management (28%) and emergency services (48%). More Asians (66%) and Hispanics (52%) used individual outpatient services than Whites and Blacks. It is interesting to note that among the users of each type of service, the difference in the amount of use among the racial and ethnic groups is not statistically significant.

TABLE 2—Percent and Patterns of Use among Users by Type of Public Mental Health Services in San Francisco County and Santa Clara County by Ethnicity or Race, Fiscal Year 1987–1988

Service	Asian (n = 3825)	Black (n = 3895)	Hispanic (n = 3842)	White (n = 15146)	Total (n = 26708)
Percent of use[a]					
Inpatient	2 (70)	2 (93)	4 (140)	4 (531)	3 (834)
Case management	20 (769)	28 (1087)	22 (829)	24 (3564)	23 (6249)
Individual outpatient	66 (2540)	37 (1448)	52 (1997)	45 (6876)	48 (12 861)
Emergency services	22 (858)	48 (1860)	34 (1324)	38 (5727)	37 (9769)
Amount of use[b]					
Inpatient days	12.64 (13.41)	10.37 (11.80)	13.07 (14.21)	12.00 (12.89)	12.05 (13.05)
Case management hours	4.92 (13.55)	4.02 (9.25)	4.59 (13.52)	6.50 (20.68)	5.62 (17.65)
Individual outpatient visits	9.71 (8.50)	8.35 (10.11)	9.04 (10.51)	10.76 (12.05)	10.01 (11.02)
Emergency services visits	1.64 (1.36)	1.76 (1.65)	1.49 (1.15)	1.68 (1.60)	1.66 (1.54)

[a]Numbers in parentheses are number of users.
[b]Numbers in parentheses are standard deviations.

Data Analysis

The basic data description suggests that differences in the use of the four types of public mental health services among the four populations could be in the percentage of initial use, because there are no significant differences among the users once they are engaged in the service. This preliminary information suggests that one should analyze the data in two stages.

The first stage is to test for the possible ethnic differences in initial use of different types of mental health services. As shown in Table 2, not everyone uses all four types of service. Among the public mental health service users, only 37% used emergency services, 3% used inpatient, 23% used case management, and 48% used individual outpatient services. To differentiate between initial users and nonusers, the dependent variable was designated as 1 for the users and 0 for the nonusers. Logistic regression was used to analyze the selection of services issue.

The second stage of the analysis was to test and measure the differences in the amount of service use once an individual was a user of a given type of service. Because there was a wide variation in the amount of usage, the usage variables were expressed in logarithmic form to adjust for skewness in the distribution. We used least-squares analysis to estimate the amount-of-use equations.

To estimate the real differences among the four ethnic and racial groups, it was important to account for all differences attributable to sociodemographic factors and mental health status, such as age, education, marital status, diagnosis, and county of residence. Although we do not have adequate data on users' income and health insurance status, public mental health services are paid by public funds and a large majority of the users are low income individuals. Thus, the absence of these two variables would not cause bias for the estimated coefficients.

To measure the possible differences among the ethnic populations in the sample, three dummy variables were introduced: Asian, Black, and Hispanic. White is the deleted group used for comparison. We also introduced a dummy variable representing Santa Clara County to account for possible system differences. Because of high correlations between language and ethnicity, we deleted the language variable in the final model.

Results

Table 3 shows the logit analysis of the full model for the probability of using these four types of mental health services. Table 4 shows the least-squares results from the users' sample for these four types of mental health services. All of the explanatory variables (except for GAS) are in categorical form. The comparison groups consist of individuals with the following characteristics: male, White, married, fewer than 8 years education, unemployed, aged 18 to 24, nondisabled, with DSM-III adjustment disorder, and from San Francisco.

To understand the actual magnitude of the effect of these explanatory variables, including the ethnic and racial differences, we calculated each marginal effect (marginal probability) on the use of public mental health services.[15] Only the statistically significant coefficients were calculated with their marginal effects. These results also appear in Table 3.

Results are discussed by the type of mental health service presented in both Tables 3 and 4, which include the probability of initial use by ethnic or racial differences and the amount of use.

Emergency Services

Table 3 indicates that Asians and Hispanics had less probability (17% and 4%, respectively) of using emergency services than Whites, while Blacks had a slightly higher probability of using emergency services than Whites. Individuals residing in Santa Clara County were 30% less likely to use emergency services than individuals in San Francisco. As shown in Table 4, after the initial use of emergency services, there were no statistically significant differences in amount of use among Asians, Blacks, and Whites. However, Hispanics used 4% less services than Whites. Again, among initial users of emergency services, Santa Clara had 11% fewer users than San Francisco.

Other results in the model indicate that males who were never married, had some high school education (9 to 12 years), were aged 18 to 24, and were diagnosed with alcohol or drug related problems had a higher probability of using emergency crisis intervention. Those with higher GAS scores were less likely to use emergency services. Among the users of emergency services, fewer of the above variables were significant with regard to amount of use, except that individuals diagnosed with schizophrenia and affective disorders used greater amounts of emergency service.

Inpatient Services

The results indicate that Asians had a lower probability (2%) of using public inpatient services. There are no statistically significant differences among

Blacks, Hispanics, and Whites in terms of initial use of inpatient services. Individuals in Santa Clara County had a higher probability of using inpatient services than those in San Francisco. Among inpatient service users, there were no statistically significant differences on amount of use among the four ethnic or racial groups, although patients in Santa Clara County had a 25% shorter length of stay as inpatients than those in San Francisco. Other variables in the model indicate that never married or widowed individuals had a higher probability of using inpatient services, while employed individuals, individuals in school, and the elderly had a lower probability of using these services. Individuals diagnosed with alcohol or drug problems, schizophrenia, affective disorder, and other psychotic disorders had a higher probability of using inpatient services than individuals with adjustment disorder, the deleted group. The higher the GAS score, the less likely individuals were to be admitted to inpatient care. Individuals with physical disabilities were less likely to use inpatient care than the nondisabled. It should be noted that the small magnitude of difference in the probability of using inpatient services among ethnic and racial groups or counties is due to the small percentage of individuals who used inpatient services.

Case Management Services

Case management has become a popular and important form of community mental health service. Case management helps a client gain access to needed medical, social, and educational services. It involves evaluation, development of a service plan, monitoring of the program and movement within the system, and intervention as needed to ensure the availability of the needed services. The results in Table 3 indicate that Asians and Blacks had less probability of using case management services than Hispanic and White individuals. Individuals in Santa Clara had a lower probability (10%) of using case management services than those in San Francisco. Table 4 indicates no significant difference in amount of use among those initially using case management. Individuals with schizophrenia or affective disorder had very high probabilities (31% and 16%, respectively) of initial use of case management. They also used it more often, as did those with adjustment and other psychotic disorders. The higher the GAS score, the lower the probability of case management use.

Individual Outpatient Services

About 50% of the two counties' public mental health clients used individual outpatient mental health services. Among the ethnic and racial populations, Blacks had a lower probability (2%) of using outpatient care than Whites. Asians and Hispanics, on the other hand, were more likely to use individual outpatient services than Whites. Individuals in Santa Clara had a higher probability (8%) of using individual outpatient treatment than those in San Francisco. As to amount of service used, Blacks and Hispanics used 18% and 11%, respectively, less service than Whites, while Asians used 6% more of these services than Whites (see Table 4).

Younger groups had a higher probability of using individual outpatient services than older persons. Individuals with alcohol or drug problems, schizophrenia, and other psychoses had a markedly lower probability of using individual services, while those with neuroses or personality disorders had a higher probability of using individual services. The higher the GAS scores, the lower the probability of using individual services.

Discussion

The findings of this study confirm that there are differences among racial and ethnic groups in choosing public mental health services. Asians had a lower probability than Whites of using emergency, inpatient, and case management services, and a higher probability of using individual outpatient services. Blacks were less likely than Whites to use case management and individual outpatient services, but were more likely to use emergency services. Hispanics had a higher probability of using case management and a lower probability of using emergency services, but there was no significant difference between Whites and Hispanics in use of inpatient and individual outpatient services.

Although there were significant differences in the selection of services among ethnic and racial minorities, there were no significant differences in the amount of either inpatient or case management use. However, in individual outpatient services the differences among ethnic groups continued to exist. Asians used more individual outpatient services, while Blacks and Hispanics used less than Whites. Hispanics used less emergency service than Whites.

Results from the present study provide cause for continuing concern about minority utilization. Utilization by Blacks appears especially problematic, because this group appears to rely more on emergency service and less on case management and outpatient care than Whites. Hispanics in psychotherapy attended fewer sessions than Whites, but in other respects Hispanic utilization patterns were more encouraging. Asians have chosen and used services in ways that were at least as favorable as Whites, and, in most instances, more favorable. Researchers and service planners should avoid generalizing utilization patterns from one minority group to another.

There is a distinct difference between individuals in San Francisco and Santa Clara County. Individuals in Santa Clara County had a lower probability of using emergency services and case management and a higher probability of using inpatient and individual outpatient services than those in San Francisco. Santa Clara County individuals used lesser amounts of emergency, inpatient, and case management services than users in San Francisco. The differences between areas could be explained by the decentralized nature of providing public mental health services in California. The flexibility in the state's funding policy allows each county to deliver different levels and types of mental health services. In San Francisco, the city allocates very limited resources to inpatient services and places a greater emphasis on the broad use of case management as an appropriate service modality. On the other hand, Santa Clara County provides more generous inpatient services and has created eight new community mental health outpatient service centers for Asian and Hispanic minorities. Consequently, patients in public health systems in San Francisco and Santa Clara counties receive different types and amounts of mental health services. □

Income, Race, and Surgery in Maryland

Alan M. Gittelsohn, PhD, Jane Halpern, MD, and Ricardo L. Sanchez, MD

ABSTRACT

Background. We describe common surgical and medical hospital admission rates for Maryland residents, exploring systematic effects of race and income.

Methods. The data comprise Maryland hospital discharges and population estimates for 1985 to 1987. Patient income is the race-specific median family income of residence zip code. Logistic regression is used to measure incidence by race, income, and residence for surgical and medical reasons for admission.

Results. Population rates for discretionary orthopedic, vascular, and laryngologic surgery tend to increase with community income levels. Coronary and carotid artery surgery rates are two to three times higher among Whites. The more discretionary the procedure, the lower is the relative incidence among Blacks. By contrast, admission rates for most medical reasons decline with increasing income levels and are elevated among Blacks. The affluent receive coronary artery procedures whereas the poor are hospitalized for coronary artery disease.

Conclusions. Blacks and the poor appear to have higher illness burdens requiring hospital care. Discretionary surgeries have a White predominance and increase with income; medical admissions have a Black predominance and decline with income. Race and community income level are important factors in differential hospital utilization rates. (*Am J Public Health.* 1991;81:1435–1441)

Introduction

Significant variations in the incidence of common surgical procedures have been observed in the United States, Canada, and Western Europe over the past 50 years, a general finding being intermediate to high variability in surgical rates between population groups.[1–9] The predominant explanation for geographic differences has emphasized physician practice styles. Populations may differ in disease prevalence, demographic characteristics, access to care, and medical resources. These factors are confounded because measurement in geographic studies involves place of residence or exposure. The result is that a high or low surgical rate for a community cannot be ascribed directly to morbidity, access, or medical supply variables. High-rate areas have been suggested as representing "unnecessary" surgery and low rate areas as "underserviced." Underservice has been proposed to explain the equal distribution of "appropriateness" of care observed for Medicare patients receiving procedures in high- and low-rate communities.[9]

Unresolved questions pertain to the interpretation of variations in surgery rates in terms of health benefit, questions that cannot be answered with incidence data alone. The efficacy of some procedures and indications for appropriate intervention have yet to be established. Studies of the variability of surgical opinion report a lack of concordance for several common surgeries.[10] Few procedures have been studied by randomized clinical trials to assess benefits and delineate indications for which benefits might be derived. Without efficacy studies, it is not possible to determine whether a high-rate area indicates overuse or a low-rate area underservice. We include common medical reasons for hospital admission for comparison and as indicators of need for surgery. Our purpose is to describe use of surgical and medical services by race, income, and geographic area in Maryland.

Methods

Data Sources

We derived surgical and medical admission rates from 1985 to 1987 discharge abstracts, collected by the Hospital Services Cost Review Commission (HSCRC), for Maryland patients admitted to acute care hospitals. The abstract includes age, race, sex, zip code of residence, procedures, diagnoses, and diagnosis-related group (DRG). Records for Maryland residents treated in Washington, DC, and northern Virginia hospitals in 1985 are included. These are important for Washington suburbs, where patient migration into the District of Columbia is common, particularly for specialized care provided in the medical centers of the city. Surgical cases are classified by the most important procedure and medical admissions by DRG. We use "incidence" as the count of occurrences of a surgery or DRG. The admission rate is incidence relative to the population at risk by age, sex, race, income, and zip code of residence, irrespective of the hospital providing care.

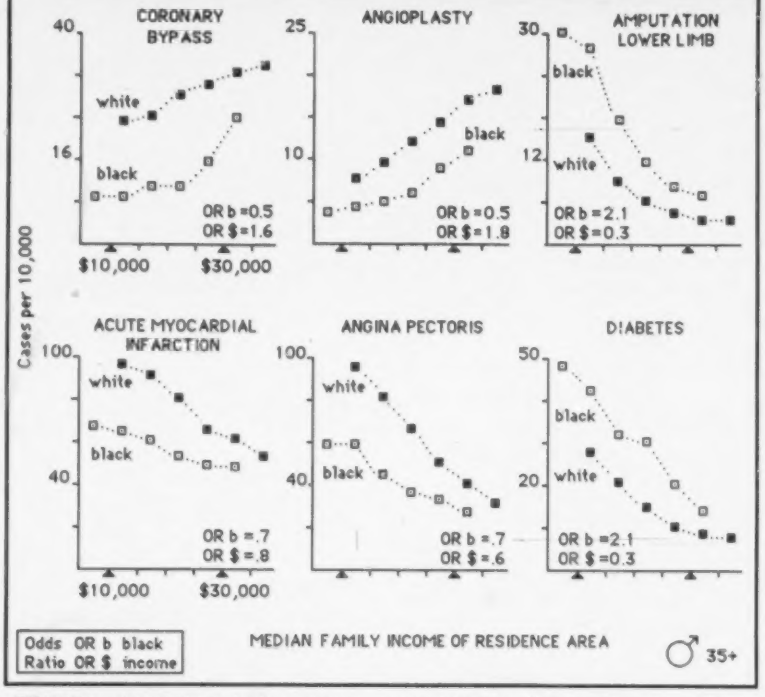

FIGURE 1—Hospital admission rates by race and income, Maryland men aged 35+, 1985–1987.

Population

Maryland's 1986 population of 4.4 million was distributed in 485 zip code areas, grouped into 115 areas by combining adjacent small zip codes. Populations were derived from the 1980 census and 1986 county projections by age, race, and sex.[11] Nonwhite nonblacks constitute under 5% of non-Whites and are classified as Black. Blacks, who make up 27% of Maryland's population, predominate in low-income areas constituting the majority of the poor. Appalachian western counties and high-income suburbs have few Blacks. Four Baltimore City zip codes are 90% White and three are more than 90% Black. We used race-specific median family income of zip code of residence in our analysis because income was not available in the patient record. Zip code median incomes for Whites ranged from $7000 to $58 000, medians for Blacks averaged one third less. We estimated separate medians by race because of wide income gaps between Blacks and Whites living in the same zip code. Variability within areas limits the value of group median income, possibly resulting in attenuation of relationships of surgery and DRG rates with income. There were no ready means for projecting 1979 census incomes to 1986 to account for declines among the poor and increases among the wealthy. Few problems arose in uniformly poor areas and in homogeneous suburbs. Problems did occur in zip codes with wide income variation and pockets of affluence or poverty.

Statistical Methods

The indirect surgical rate for an area is the ratio of observed/expected cases; expectations were based on Maryland age-specific rates. The distribution of 115 area case ratios for a procedure around the state average of 1.0 includes random and systematic components of variance described by MacPherson.[6] The random component depends on the number of cases, whereas the systematic component (SCV) reflects systematic effects above random variation. Incidence is related to multiple factors through coefficient beta in logistic regression.[12] A case is coded "1" and a population datum "0" within age, race, sex, income, and area classes. The estimate b and its standard error SE(b) provide a test of the hypothesis of no effect of the factor. The odds ratio OR = Exp[rb] is relative incidence over the range (r) adjusted by the factors in the model. With r = 1, OR(male) compares males with females (M = 1 and F = 0) and OR(Black) compares Blacks with Whites (B = 1 and W = 0). Age is coded in 10-year groups from under 5 years to 75 years and over. For income coded in $1000 units, we used r = 20 with an interval of 10 to 30 because there were few Whites living in areas with a median below $10 000 and few Blacks living in areas above $30 000. OR(income) = Exp[20b] compares areas with medians of $30 000 with areas with medians of $10 000.

Race and Income Trends

We use first order models for simplicity of presentation. Small deviations of the betas from 0 and minor differences between slopes are often significant when regression is applied to large populations. Figure 1 shows examples of surgical and DRG admission rates with differing income trends by race. Odds ratios are included for comparison with the trends. The rates pertain to men over 35 years of age, with the 115 zip code areas grouped into $5000 income classes. Coronary bypass and angioplasty rates increase over 60% with income for both races. With an OR of 0.5, Blacks have lower rates within each income class, indicating presence of a race effect over and above income. Nonparallel income trends by race are seen, with race differences that are pronounced among low-income groups and reduced among higher income groups. By contrast, admissions for acute myocardial infarction and angina pectoris decline with income and are reduced among Blacks. Thus, coronary artery disease is high among the poor and coronary artery surgery is high among the more affluent. A different set of relationships is present for diabetes and the complication of limb amputation for metabolic or endocrine reasons. The income OR of 0.3 indicates marked declines in diabetes and amputation rates over incomes and the Black OR of 2.1 indicates twofold higher rates among blacks. The race–income interactions are small but statistically significant. Their introduction into logistic models adds complexity without clarification. The income OR is an average for the races and the Black OR is an average over incomes.

Results

Small Area Variation in Surgery Rates

Figure 2 illustrates geographic distributions with frequency histograms of case

ratios for Whites in the 115 Maryland areas. The distributions describe total variation, including random components and SCVs. More than half of the areas have few Blacks, particularly suburban, rural, and western areas. Heterogeneity is reduced by limiting the figures to Whites. We include common surgeries and surgeries with low and high geographic variance. Coronary bypass, cholecystectomy, and hysterectomy are the leading Maryland surgeries based on total hospital charges per capita.

Procedures among Women

Mastectomy (simple and radical) had the lowest variance of the surgeries studied (SCV = .03). The low variance reflects uniform incidence and detection of breast cancer and medical consensus as to its management. Reduction mammoplasty had the highest variance observed (SCV = 1.07), its use increasing markedly with income. Generally, cosmetic procedures have high systematic variances based on patient demand and income. Cesarean section had low geographic dispersion, indicating similar obstetrical approaches throughout the state. Hysterectomy had moderate variance (SCV = .08). Cholecystectomy varied twofold between moderate-income South Baltimore and affluent North Baltimore. Variation may be explained by different social factors, approaches to management, or incidence of cholelithiasis in these populations.

Procedures among Men

Prostatectomy and inguinal hernia repair were nearly uniform across the state. The low SCVs suggest uniform prevalence and apparency of indications, agreement as to management, and few barriers to care. Nondiscretionary appendectomy had an outlier in Cambridge, with eight times the rate of nearby Annapolis. The high surgery rate may be due to high incidence of appendicitis, to a lower threshold for surgery, or to a high rate of false positive indications. Laminectomy was discretionary, with incidence varying fourfold between southwestern Baltimore and the Eastern Shore. The latter region may be underserved by orthopedic surgeons. Differentiating overuse in one area from underuse in another implies study of appropriateness and geographic and occupational variations in spinal disk problems. Coronary bypass had high geographic variability (SCV = .63). Explanation requires distinguishing among disease effects, access, referral, and criteria for case selection.

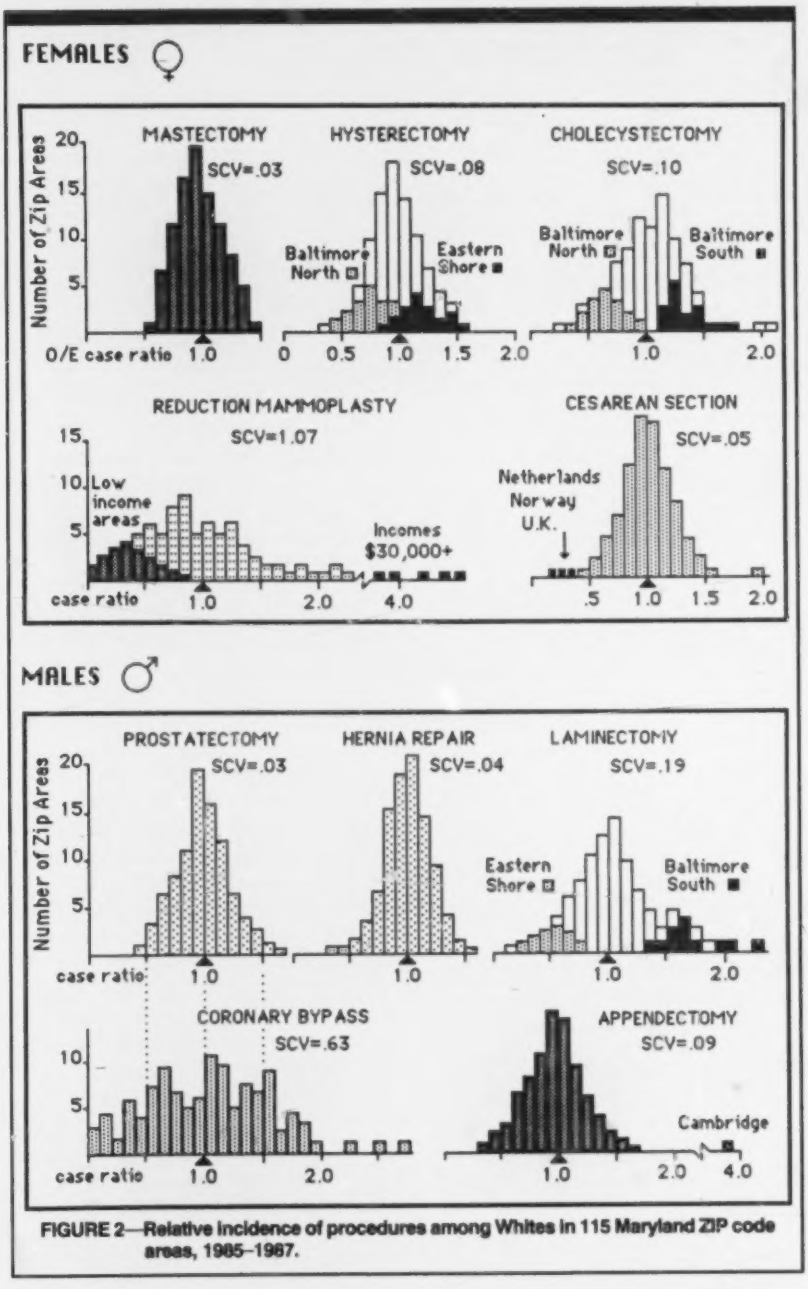

FIGURE 2—Relative incidence of procedures among Whites in 115 Maryland ZIP code areas, 1985–1987.

Variability of case ratios among the 115 small areas was observed for each procedure by statistical test, including low-variation mastectomy and inguinal hernia repair.[9,13] For common surgeries, small deviations from randomness are significant because of sample size alone. Tests for uniformity of rates provide little new information because the null hypothesis is almost always rejected. Local variations in surgical practice were present for many procedures. The distributions reflect reported services as delivered in Maryland during the study period. The low variance of cesarean section rates (SCV = .05) points out a limitation of small area analysis. The state average is a yardstick for comparing the 115 areas, not an objective standard. The Maryland cesarean rate is two to three times that of Western European countries.[14] We found no definitive results relating obstetrical practice differences to birth outcomes on a population basis. A similar situation held for many discretionary surgeries.

TABLE 1—Relative Incidence of Common Surgeries: Odds Ratios for Race and Median Family Income, Maryland, 1985–1987

Sex	Procedure	No. of Cases	Odds Ratio: Income (high/low)	Odds Ratio: Black (B/W)
Both	Sinus procedures	7781	1.23*	0.80*
	Total hip replacement	7761	1.22*	0.73*
	Tonsillectomy	22 743	1.13*	0.44*
	Hemorrhoidectomy	12 105	1.05	0.69*
	Appendectomy	13 112	1.01	0.64*
	Gastrectomy	2972	0.68*	1.47*
	Amputation of limb	7077	0.29*	2.03*
Female	Cosmetic surgeries	8135	4.53*	0.30*
	Operations on foot and toe	3655	1.58*	1.97*
	Mastectomy	6665	1.49*	0.96
	Thyroidectomy	2857	1.48*	1.51*
	Hysterectomy	28 891	1.21*	1.42*
	Cholecystectomy	15 776	0.54*	0.56*
Male	Angioplasty	3439	1.82*	0.52*
	Coronary bypass	7209	1.62*	0.45*
	Laminectomy	7441	1.42*	0.49*
	Prostatectomy	17 782	1.12*	0.99
	Inguinal hernia repair	14 628	1.02	0.78*
	Carotid endarterectomy	2244	0.83*	0.31*

Note. Odds ratios are based on logistic regression of surgery by age, race, sex, and income. Cosmetic procedures include blepharoplasty, rhinoplasty, mammoplasty, and facial rhytidectomy.
*$P < .01$

Surgery Rates by Income and Race

Table 1 is a summary of logistic regressions for common surgeries showing ORs for income and race. Sex-dominant procedures such as mastectomy for women and hernia repair for men were computed for one sex. Most surgeries increased or remained constant over income levels. Cosmetic surgery rates exhibited fourfold and higher variation between low- and high-income areas, with access explaining the difference. For vascular procedures, the income OR was 1.8 for angioplasty, 1.6 for coronary bypass, and 1.5 for coronary angiography. The income ORs were 1.6 for sinus procedures and 1.3 for tonsillectomy. Orthopedic procedures involving hip, knee, and spine increased with income. Inguinal hernia repair, appendectomy, and prostatectomy were not related to income. The income OR was 0.5 for cholecystectomy, one of the few discretionary surgeries that declined with income. Women in high-income areas had half the gallbladder surgery rate of women in low-income areas. The lowest surgical income OR was 0.3 for nondiscretionary amputation of limb for endocrine and metabolic reasons. Many of these cases were diabetics with peripheral vascular disease.

Whites had higher rates than Blacks for most discretionary surgeries. The low Black OR for elective surgeries is explained by income or by deselection of Blacks for the procedures. Hernia and appendectomy rates were lower among Blacks. Laryngologic surgery was elevated among Whites. Tonsillectomy rates were 29 per 10 000 for Whites and 13 for Blacks. Orthopedic surgery was more common among Whites. The laminectomy Black OR of 0.5 indicates that half as many procedures were performed among Blacks as among Whites. Adjusted by age, sex, and income, the 1:2 Black to White ratio implies that race was a contributing factor per se. Race differences in vascular surgery were measured by two to three times higher rates among Whites for angioplasty, coronary bypass, and carotid endarterectomy. Prostatectomy and mastectomy exhibited no race difference. Gynecologic surgery was higher among Black women, with a Black OR of 1.2 for hysterectomy. Foot operations, including excision of bunion and arthroplasty, were twice as common among Blacks. Either Blacks had more foot problems requiring care or they received more inpatient surgery because of differing medical practice. Nondiscretionary gastrectomy and limb amputation were elevated among Blacks (ORs = 1.5 and 2.0). Discretionary aspects of common vascular, orthopedic, and laryngologic procedures suggest that lower rates for Blacks were related to referral and access rather than morbidity.

Medical Admissions

Table 2 shows ORs for common medical DRGs. Persons living in low-income areas were more likely to be hospitalized for medical reasons than persons in high-income areas. This pattern suggests an income relationship whereby the poor have a higher incidence of conditions requiring hospital care. For all medical DRGs, the income OR of 0.6 was a decline of 40% over incomes from $10 000 to $30 000 per year. Angina pectoris, hypertension, and heart failure rates decreased by more than half with income. The income OR was 0.3 for pneumonia and 0.2 for bronchitis and asthma. Rates for alcohol-related DRGs declined by 75% with income, in part reflecting use by those privately insured of treatment facilities not in the HSCRC database. Gastrointestinal obstruction, hip fracture, and medical back problems were among the few common medical DRGs that did not decline in incidence with income.

Women predominated for hip fracture, bowel inflammation, urinary tract infection, hypertension, and diabetes. The high female rates for hip fracture occurred among Whites but not Blacks. Men predominated among heart disease (male OR = 2.0 for acute myocardial infarction). Male-to-female ORs above 3.0 were noted for cirrhosis of the liver and alcohol-related DRGs. Although Blacks had lower surgery rates than Whites, the total medical admission rate was 22% higher for Blacks. Blacks had high ORs of 2.0 for diabetes, 3.0 for hypertension, 2.3 for alcohol-related DRGs, and 5.4 for red blood cell disorders, a difference due to sickle cell anemia. An exception was hip fracture (Black OR = 0.4 for women and 0.8 for men). Among cardiovascular conditions, Whites had higher rates for acute myocardial infarction, angina pectoris, and arrhythmias and Blacks had higher rates for heart failure.

Discussion

Explanations for geographic variations in surgical and medical admission rates have emphasized the role of physician practice style differences reflecting medical uncertainty regarding optimal treatment regimens. Our results indicate that race and income may confound differences between small areas, particularly in states with heterogeneous populations. These demographic factors may influence medical need in terms of disease prevalence and severity as well as the demand

for and access to primary and secondary care. The surgery rate for a community is based on multiple factors, including demography, morbidity, access to care, referral practice, physician decisions concerning patient management, and medical resources.

Generally, small area data are unavailable for incidence or prevalence of conditions leading to hospital care. An exception is cancer measured by mortality statistics and tumor registries. Objective definition of disease by pathology, high levels of ascertainment, and concordance among physicians concerning management lead to correspondence between surgical rates and breast cancer incidence. Race differences in mastectomy rates may be related to incidence of breast cancer by income operating through differences in fertility. A review of the role of pregnancy history reports protective effects of early pregnancy and high risk among nulliperous women.[15] Deferred child bearing and lower fertility among the more affluent may explain the income OR of 1.5 for mastectomy, one of the few nondiscretionary surgeries increasing with income. Morbidity explains the distribution of mastectomy. By contrast, there is little information on the occurrence of cholelithiasis, prostate hypertrophy, uterine fibroids, and other indications for common surgeries. Morbidity cannot be ruled out as a determinant of surgical rate differences between communities. Uncertainty holds for the relative contributions of disease factors, selection of cases for particular types of care, access, referral networks, and physician practice styles.

Access to care involves patient perceptions, financial means to secure care, availability of care, and the referral network to surgeons, which, if constrained, may result in low surgery rates. Such constraint may hold for Maryland Blacks for elective, vascular, orthopedic, and laryngologic surgery. Most surgeries exhibit either a positive relationship or no relationship to income. An implication is that access factors related to income are determinants of use of discretionary procedures. Among common discretionary surgeries, cholecystectomy has the largest decline with income. The decline for Whites is consistent with a disease hypothesis whereby residents of high-income areas have reduced incidence of cholelithiasis. Management of gallbladder disease and referral behavior in low-rate areas may restrict surgical intervention. Residents of affluent communities are not constrained in access because of limitations in income and insurance coverage. Cholelithiasis increases with obesity and is reduced among higher social classes.[16] Among women, Whites have 50% higher cholecystectomy rates than Blacks despite lower incomes and higher obesity levels among Blacks.[17] Race differences in cholecystectomy may be due to reduced occurrence of gallstones among Blacks or to deselection of Blacks for surgery. Blacks have lower rates for elective, vascular, orthopedic, and laryngologic procedures, whereas parity is seen for prostatectomy and a 22% excess for hysterectomy. The more discretionary the procedure, the lower the relative incidence among Blacks. Discretionary aspects of vascular, orthopedic, and laryngologic procedures and lack of evidence supporting morbidity differences by race suggest that the low rates for Blacks relate to referral and access. There are no definitive studies documenting race differences in prevalence of lesions of coronary and carotid arteries. Mortality data indicate that Blacks have similar or higher death rates than Whites for ischemic heart and cerebrovascular disease. Access, referral practices, and case selection may explain the two to three times higher incidence of vascular surgery among Whites.

Rates for most medical DRGs decline with income, a finding consistent with higher morbidity among low-income groups. Diabetes, bronchitis, and asthma and pneumonia rates decline by two thirds with income. Since diabetes and asthma are thought not to depend on social class, medical management may underlie the declining hospital rates with increasing income levels. In contrast to lower Black rates for most surgical specialties, Blacks have higher rates than Whites for many common DRGs. The relationship between illness measured by hospital admission and surgical use is variable. There is a twofold higher incidence among Blacks for diabetes and the complication of limb amputation for endocrine and metabolic reasons. Coronary bypass, angioplasty, and angiocardiography have similar patterns of use, increasing with income and significantly elevated among Whites within each income group. Race effects are present over and above income. Coronary artery surgery (CAS) increases with income, whereas coronary artery disease (CAD) declines. High CAD rates occur in

TABLE 2—Relative Incidence of Diagnosis-Related Groups (DRGs): Odds Ratios for Race, Sex, and Median Family Income, Maryland, 1985–1987

Diagnosis-Related Group/Medical DRG	No. of Cases	Odds Ratio		
		Income (high/low)	Male (M/F)	Black (B/W)

*$P < .01$

low-income areas and high CAS rates in high-income areas, a discordancy between treatment and need as measured by these means. Blacks have 20% lower rates for CAD and markedly lower rates for CAS (Black OR = 0.4 for coronary bypass and 0.5 for angioplasty). The race difference for CAS is highest among low-income groups and approaches parity among the more affluent. Maryland Blacks have access to hospital care for medical reasons and are deselected for discretionary procedures in at least three surgical specialties. Morbidity explanations for most of the medical and surgical admission rate differences by race and income remain to be elaborated. A general conclusion is that the medical care system of Maryland constrains the use of discretionary vascular, orthopedic, and laryngologic surgery by the poor and by Blacks.

Incidence rates based on hospital abstracts and population projections have several limitations. Data problems are inherent in an administrative health data system with 55 participating hospitals. A major constraint is inability to link records for multiple admissions of a patient. Patients seeking care in other states are not reported. A check of border areas does not indicate abnormal rates. No information is available on quality of abstracting. Formal errors are present with impossible combinations of ICD codes by sex and age (e.g., men with gynecologic diagnoses and the aged with perinatal conditions). Errors of this type are rare compared with factual errors undetected by editing. Experience in other settings may be relevant. After the swine flu affair, record reviews of abstracts with Guillain-Barre syndrome and abstracts with tuberculosis as comorbidity revealed nearly 100% false positives due to miscoding.[18] A reliability study comparing records with independent reabstracts found three-digit ICD agreement ranging from 34% for chronic ischemic heart disease to more than 90% for surgical diagnoses.[19] It is likely that error rates are now reduced through more careful scrutiny and use of records in reimbursement. There are uncertainties regarding populations and assignment of residence. There are abstracts with zip codes not in the postal directory and no zip codes for the homeless. Baltimore's Central Post Office is zip 21203 coded for patients by HSCRC but with no census count and over 5000 PO boxes, the size of a town. Questions pertain to 1986 county projections applied to small areas because population growth and loss rates are not uniform for zip code areas within Baltimore City or suburban counties. Use of zip code median income for individual patient income is a major, unavoidable limitation. As unassembled intelligence, the data require caution in drawing conclusions. For these reasons, we emphasize large differences not likely to be explained by artifacts of measurement.

We used population rates because of epidemiological interest and concern regarding selection bias with inpatient data. Population rates are resultants of morbidity, access, and selection factors, whereas hospital rates relate to preselected inpatients. Case fatality depends on treatment and prognosis, with clinical details on severity not routinely available. Two recent inpatient studies illustrate ambiguity due to possible selection bias. A case fatality study for uninsured patients assigns prognosis using diagnosis, age, race, sex, and comorbidity.[20] Higher death rates are reported for the uninsured. The authors note that the mortality difference "also could be due to differences in severity of illness between the uninsured and privately insured," a reference to selection bias. It is plausible that the uninsured defer seeking care and have less favorable prognoses at time of hospitalization. A CAS study explores "whether there are different procedure rates for black patients once they are hospitalized for serious cardiovascular conditions."[21] The series consists of patients with coronary artery procedures or with principal diagnosis of circulatory disease, including ischemic heart disease (IHD) and non-IHD circulatory diseases. Non-IHD patients with hypertension or cerebral hemorrhage ordinarily do not receive CAS. The authors show CAS rates of 0.4% for non-IHD and 39% for chronic ischemia patients, a hundredfold difference. There is an excess of Blacks in the low-risk groups. In Maryland, most CAS cases have coronary ischemia with selection and surgery scheduled before, not after, admission. Thus, Pr{CAS|coronary ischemia & CAS scheduled} is about 1 and Pr{CAS|hypertension or stroke} is about 0. We concur with the finding of race differences in use of CAS but based on population studies. Population-based rates avoid some of the uncertainties involved in measuring risks among preselected patients. Central issues in population studies are factors leading to selection for hospitalization.

We have described variations in surgical and hospital care by race and income for Maryland during 1985 through 1987. Our results show that the more discretionary the procedure, the lower its relative incidence among Blacks and the poor. Admissions for common medical reasons are elevated among Blacks and decline with increasing income for both races. Varying rates between communities reflect the interplay of diverse factors, including patient behaviors, morbidity, access, physician practice styles, referral, and resource availability. Each factor has different implications for strategies designed to reduce health care costs, to improve quality of care, and to help ensure equitable allocation of care. Incidence data using hospital records and population estimates alone cannot clearly distinguish between these effects and can only provide indicators of unexplained variability and measures of low and high occurrence rates. Incidence data can be used to target potential problems, to assist in assigning priorities for special investigation, and to provide descriptions of medical care impacts on population groups. □

Effects of Budgeting on Health Care Services in Dutch Hospitals

Anton F. Casparie, MD, PhD, and Dick Hoogendoorn, MD, PhD

ABSTRACT

Background. In 1983 hospital budgeting was introduced in the Netherlands. We studied the effect of the enactment of budgeting on the efficiency and effectiveness of health care.

Methods. In four different age groups, the admission rate, length of stay, type and number of surgical inpatient procedures, and hospital mortality were measured in all short-term hospitals from 1977 through 1988. Data were standardized by age and sex.

Results. For the total population, the hospital admission rate and the operation rate decreased after 1982. However, for the subgroup of patients beyond the age of 65 both rates are still on the rise, but the increase in the admission rate for elderly patients has slowed significantly since 1983. The tendency toward a shorter length of stay, together with the diminished admission rates, led to a 22% decrease in standardized hospital days between 1982 and 1988. The severity of the operations increased. Most operations performed on elderly patients were aimed at improving the quality of their lives rather than lengthening their life expectancy. The hospital mortality rate decreased in all age groups.

Conclusions. The findings suggest that modern medicine in the Netherlands has become more efficient and more effective. Better health care for older patients was achieved within the same budget. The tendency toward more efficiency by hospitals has been reinforced since 1983. (*Am J Public Health.* 1991;81:1442–1447).

Introduction

In the Netherlands, a country with nearly 15 million inhabitants, as in many other countries, the government and policymakers have been concerned about the increase in the costs of health care in the past few decades. One effort by the Netherlands to control these costs and to stimulate efficient health care was the introduction of hospital budgeting in 1983. Prior to 1983, hospitals were financed on the basis of their production output, a patient-day price depending on contracts with sickness funds.

In 1983 and 1984, a sum was allotted to each hospital, based only on what it had spent in the previous year on the treatment of both inpatients and outpatients. In this system a hospital received a global budget for all its activities.[1] Since 1985, the budget has been calculated by a combination of a fixed and a variable part. The fixed part was defined by two capacity input parameters: the number of beds and specialist units for clinical and ambulatory care. Output parameters such as number of admissions and patient days determine the variable part of the budget. This variable part was determined in advance in negotiations between hospitals and local sickness funds and depended on the expected number of output parameters. All the activities had to be carried out within this global budget. If the expenses of a certain year exceeded the budget by 5% or more without an evident explanation, the budget was decreased the following year (for more details see Maarse[1]).

The first aim of the present study was to assess how budgeting has affected the admission rate and length of stay and the frequency and type of surgical procedures. As the medical profession is the principal determinant of the use of health-care services, the effects of budgeting will ultimately be reflected by changes in the practice of medical specialists. The second purpose of this investigation was to examine the relation between budgeting and the effectiveness of care as reflected by hospital mortality.

Since 1964, in the Netherlands, the Centre for the Registration of Medical Data from Hospitals has gathered inpatient data on age, sex, diagnosis on discharge, length of stay, type of surgical procedure, and in-hospital death. All general, short-term Dutch hospitals have joined this center on a voluntary basis.

In 1982, there were 176 general short-term hospitals; 90% were private. The hospitals vary in size from 60 to 900 with an average of 300 beds (4.5 beds per 1000 population).[2] About 70% of the population (those under a specified income) is covered by compulsory insurance with the sickness funds. The remainder of the population is insured by private companies. Medical specialists work within a closed staff model: they practice full-time, usually in one hospital. The medical staff meets regularly, usually once per month. Patients have access to hospital outpatient departments staffed by specialists only through referral by general practitioners.

Anton F. Casparie is with the Erasmus University Rotterdam, Department of Health Care Policy and Management. Dick Hoogendoorn, at the time of this study, was with National Centre for the Registration of Medical Data from Hospitals, Utrecht, the Netherlands. Dr. Hoogendoorn has since died.

This paper was submitted to the journal December 20, 1989, and accepted with revisions March 13, 1991.

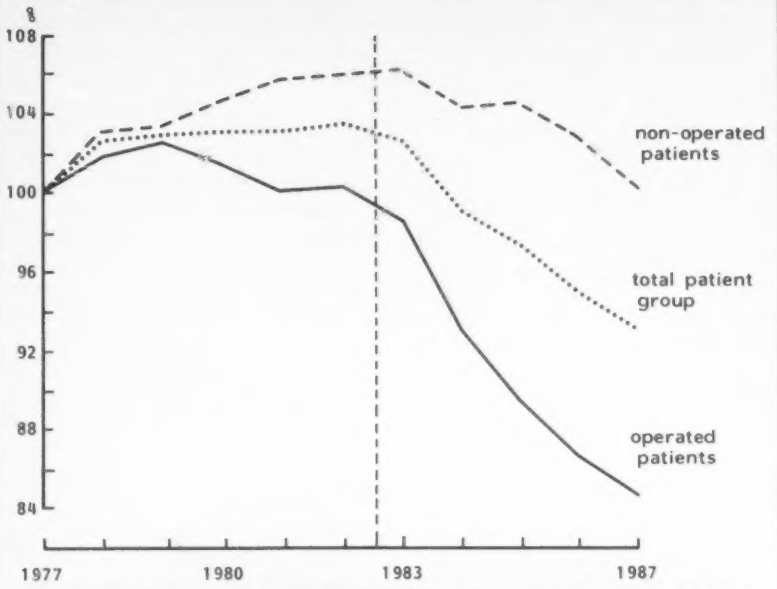

FIGURE 1—1977 age-adjusted admission rates for patients undergoing an operation (51.0/1000 population) and patients not undergoing an operation (56.2/1000 population) divided by comparable rates for each year (1977–1988) and multiplied by 100.

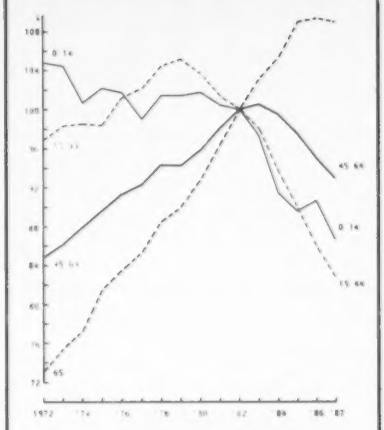

FIGURE 2—1982 admission rates for age groups 0–14 (101.0/1000 population), 15–44 (88.8/1000 population), 45–64 (123.4/1000 population), and 65 years and over (207.1/1000 population) divided by comparable rates for each year (1977–1988) and multiplied by 100.

General practitioners themselves do not have hospital admission privileges. In the Netherlands, most medical specialists work on a fee-for-service basis; for outpatient treatment of publicly insured patients, the specialist receives a fixed amount of money that covers 1 month of treatment. These arrangements remained unchanged after the enactment of hospital budgeting.

Methods

Data regarding the population were obtained from the Dutch Central Bureau of Statistics.[3] The data from the Centre for Registration of Medical Data from Hospitals have been standardized by age and sex and classified by diagnosis according to the international Who-classification, ICD-8 (international classification of diseases, eighth revision) and ICD-g-CM (ninth revision, classification of mortality). All invasive therapeutic procedures, with the exception of infusions, are classified as operations. Seven classes of surgical intervention have been weighted from 1 (easy) to 7 (very demanding), with the average length of time needed for the operation serving as the criterion of relative weight.

Following standardization, annual rates were divided by comparable rates in a given (base) year and multiplied by 100. Thus, the figures reflect percentages with the base year as 100%. The observed numbers of admitted patients and of operated patients per 1000 (y) have been regressed against the time (x) in years, for the periods 1972 through 1982 and 1983 through 1988. The slopes and the 95% confidence intervals for the differences between these slopes were determined with the Confidential Interval Analysis Program of the *British Medical Journal.*

Results

Admission Rate

For the total population, the hospital admission rate decreased after 1982 (Figure 1). The decrease seems to have set in earlier and to have been more pronounced for patients undergoing an operation during their hospital stay. Figure 2 shows the admission rates of four age groups as a percentage of the admission rate in 1982, the year before budgeting was enacted (actual admission rates are available on request). For each group, the slopes of the regression lines for the periods before and after 1983 were determined (Table 1). They represent the average annual increase or decrease in the number of admissions in these periods. The differences between these slopes and their 95% confidence intervals were calculated. After 1983, the slopes of the lines for the admission rates decreased significantly in each of the four age groups. For patients 65 and over, however, the rate continued to rise. The group of patients between 45 and 64 displays an upward tendency up to 1983 but a decline afterward. The 15 through 44 age group had already exhibited a decreasing admission rate before 1983, a tendency that becomes more pronounced afterward. The admission rate of the youngest group, from 0 to 14 years, began to decline after 1983.

Length of Stay

In the past 20 years, hospital stays have gradually become shorter (Figure 3). The slope of the curve shows no change in 1983.

Patient Days and Daily Cost

Decreased admission rates, combined with shorter stays, have led to a spectacular drop in the number of patient days (Table 2): in 1988 the number of patient days was more than one fifth lower than would be expected by applying 1982 age-specific rates to the 1988 population. About 75% of the decrease was due to a shorter length of stay and 25% to lower admission rates.

TABLE 1—Slopes of the Regression Lines of the Annual Admission Rate for 1972–1982 and 1983–1988 and Their Differences, by Age

Period	Age 0–14	15–44	45–64	65+
1972–1982	−0.36	0.48	1.79	5.37
1983–1988	−2.14	−3.11	−2.34	2.97
Difference	1.78	3.59	4.13	2.40
95% confidence interval	0.97, 2.60	2.85, 4.51	3.76, 4.46	1.36, 3.46

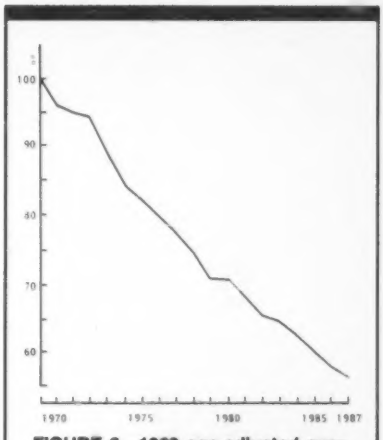

FIGURE 3—1969 age-adjusted average length of stay (18.0 days) divided by comparable length of stay for each year (1969–1988) and multiplied by 100.

Number and Rate of Operations

Table 3 shows that the number of operations performed on inpatients has decreased since 1977. The proportion of patients to undergo an operation has declined as well, and more steeply so since 1982. Figure 4 shows operation rates of the four age groups in percentages of the 1982 rate (actual rates are available on request). Table 4 presents the slopes of the regression lines. After 1983, the slopes of the regression lines were found to have decreased significantly in the age groups 0 through 14, 15 through 44, and 45 through 64, but not in the 65 and over group. For the 0 through 14 and 15 through 44 age groups, the decrease in the operation rates became more pronounced after 1982. For the group of 45 through 64-year-olds, the slight increase in operation rate before 1982 reversed to a slight decrease after that year. The operation rate of the oldest patient group, 65 and over, has, on the contrary, increased steadily.

Type and Weight of Operations

The demanding nature of operations has increased from a weight of 4.1 in 1978/1979 to 4.5 in 1985/1986. Table 5 lists the 20 operations most frequently performed on patients 65 and over in 1986, relating their frequency and age-adjusted rate in 1985/1986 to those in 1977 through 1979 for age groups below 65 and 65 and over. For all except three of these procedures, there has been an increase in frequency for the older age group; the incidence appears to have increased at a faster rate for the older age group than for the younger.

Hospital Mortality

Figure 5 expresses inpatient death rates in successive years in percentages of the 1977 death rates, separately for patients who did and did not undergo surgery while in the hospital and for age groups, younger and older than 65. The death rate appears to have gradually decreased for all four groups, with no observable effect on the budgeting requirement.

Discussion

The decline in admission rates and the decrease in the length of stay, which had already begun prior to 1982, indicate that hospitals had been trying to become more efficient for a number of years. In the past few years, an increasing proportion of operations have been performed in outpatient clinics or as day surgeries, the increase being as much as 31% between 1982 and 1988.[2] The shift is probably due to the spread of new diagnostic and therapeutic modalities applicable to outpatients and home treatment. However, in addition to improvements in operative techniques, many surgeries, such as extraction of the lens, are being done more frequently on less severely ill patients. Physicians as well as society at large have changed their attitude toward the necessity of hospital treatment for many medical conditions.

Although average length of stay had already decreased and inpatient operation rates for persons between 0 and 14 years and between 15 and 44 years, as well as the admission rate of 15 through 44 year olds, had declined even before budgeting was introduced, budgeting seems to have reinforced these tendencies. In the new budgeting system, outpatient treatment is more profitable for hospitals. However, with the fee-for-service system for medical specialists, inpatient treatment yields more income for them. Nevertheless, medical specialists know that if the expenses of a certain year exceed the budget, the budget for their hospital for the following year will be decreased; They have been willing to shift many procedures to the outpatient setting or to day surgery, a shift that involves only patients under the age of 65. We conclude that medical specialists have made well-considered decisions, probably motivated in part by guidelines and protocols. In the time period studied, there was no change in the fee of medical specialists for day surgery or outpatient care in relation to inpatient treatment. Although the hospital administration may have tried to influence a shift toward day surgery, it is the medical specialists who make the ultimate decision. The care of patients 65 and over has intensified, so the drive for efficiency has not been made at the expense of the oldest age group. Indeed, the fact that such additional care to aged patients could be provided within the budgets of the last few years is due to the more efficient treatment of younger patients.

The increasing complexity of inpatient operations, the rising number of operations performed on patients 65 and over, and the presumed poorer health of inpatients might be expected to increase mortality. However, this has not occurred. It is possible that, because of shorter hospital stays, some of the mortality has been shifted to the period after discharge. This does not seem to have occurred in the years involved, however; the proportion of inpatients discharged to a nursing home declined, the percentage of deaths occurring at home did not change, and the country's total death rate (8.4 per 1000 inhabitants in 1988[4]) declined.[5] Moreover, many of the operations most often performed on members of the older age group, such as lens extraction and total hip replacement (the very types of surgery that increased most in number), are aimed not so much at extending life expectancy as at enhancing the quality of life. Health care of the elderly has become more effective.

In spite of the growing population and an increase in the numbers of aged persons in the population, the government

Source: Last column: reference 2 and personal communication by Mr. J. U. Brouwer, senior staff member National Hospital Institute.
Note. The last column gives the costs per patient day corrected, in Dutch guilders, for inflation rates. From 1982 to 1988 the total inflation rate was 8.9%. The costs of day surgery and outpatient departments are apportioned among the number of patient days, that is, hospital costs for day surgery and outpatient care are apportioned to the costs per patient day.

was able to reduce the number of beds in general, short-stay hospitals from 69 612 to 65 510 in 1986,[6] a decrease from 4.5 to 4.2 beds per 1000 inhabitants. However, this last ratio is still higher than in most other developed countries with the exception of the Scandinavian countries.[7]

Obviously, there are more aspects of health care that have not been dealt with in this study, such as type and number of diagnostic procedures performed on inpatients and the way outpatient practices are conducted. Unfortunately, no reliable data are available on those aspects.

An accurate answer as to how much money has been saved, by the more efficient hospital use since 1983 is difficult to estimate. From Table 2 it can be calculated that the total hospital costs (number of patient days multiplied by costs per patient day) were about the same in 1982 and 1988: 11.0 and 11.2 billion Dutch guilders, respectively. However, this occurred in spite of about a 7% increase in expected patient days due to an increase in the aging population. So hospitals have been able to treat more older patients within the same budget. On the basis of demographic developments alone, the expenditures of hospitals should have been 7% more in 1988 than in 1982 (22 041 618 − 20 536 235 × 653.86), or nearly 1 billion guilders. But, the savings have been even greater because treatment of older patients is more expensive per patient day and because more expensive diagnostic and therapeutical procedures were increasingly used in hospitals during those years.

The drop in the hospital occupancy rate from 86% in 1982 to 73% in 1988 should have resulted in an even greater reduction in the number of hospital beds and, thus, in the long run, greater savings. But the total savings achieved so far are

TABLE 5—The 20 Operations Most Frequently Performed in 1986: Ratio of Age-Adjusted Rates in 1985–1986/1977–1979 for Persons Under 65 Years of Age and 65 and Over

Operation	Weight[a]	Ratio of Age-Adjusted Operation Rates for 1985–1986/1977–1979[b] 0–64	65+
Coronary bypass	7	3.77 (5375)	18.13 (2490)

Cholecystectomy	6	0.69 (8965)	0.75 (4989)

[a]1 = easy, 7 = very demanding.
[b]The numbers of operations performed in 1986 are in parentheses.

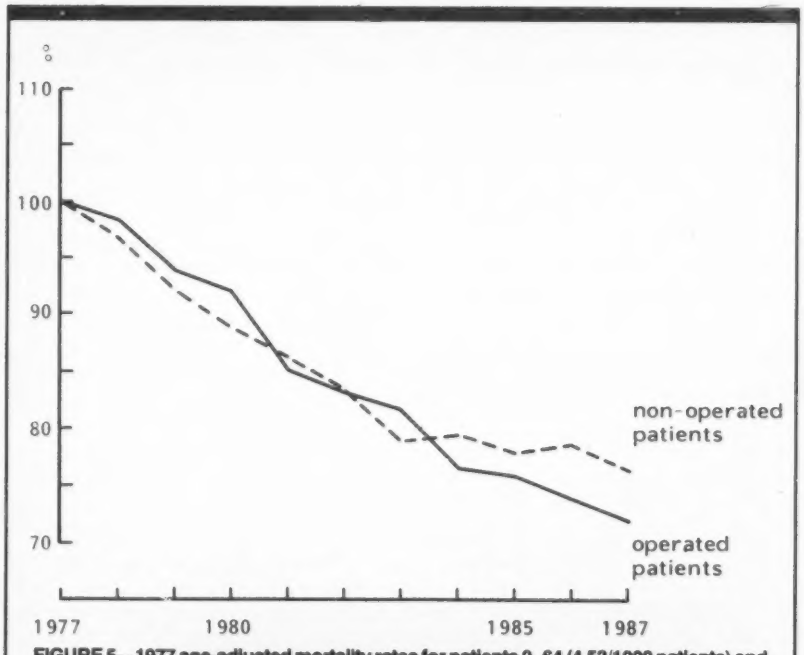

FIGURE 5—1977 age-adjusted mortality rates for patients 0–64 (4.53/1000 patients) and 65 years and over (60.6/1000 patients) undergoing an operation and patients 0–64 (21.2/1000 patients) and 65 years and over (163.5/1000 patients) not undergoing an operation divided by comparable rates for each year (1977–1988) and multiplied by 100.

already substantial. The total per capita costs of health care in the Netherlands, expressed in 1988 prices, which had increased continuously until 1983, have remained roughly at par since the enactment of budgeting.[6] The per capita costs were 2940 Dutch guilders in 1982 and 3000 Dutch guilders in 1988, or 10.3% and 9.9%, respectively, of the gross national product. The proportions of hospital costs were 59.7% and 57.8%, respectively, in these years. Indeed, the efficient use of inpatient hospital services has made it possible for other parts of the health care system, such as care for seniors, to be extended. But we must keep in mind that the population will continue to age, and that the cost of health care is bound to increase again unless the older age group, too, can be treated as outpatients or in day surgery and unless the treatment of the younger age groups can become even more efficient. Indeed, in the last 2 years, there have been indications that the financial constraints on hospitals have reached their limit or even have gone too far. In some hospitals, operating rooms and departments have been closed temporarily and, in May 1990, there was a strike by nurses because of the high work load and low income.

Conclusions

In recent years and, in particular, since the introduction of hospital budgeting in 1983, hospital services have been used more efficiently. That is probably the main reason why the rising tendency of total health care costs has leveled off since 1983. Additional care to aged patients could be provided within the budgets of the last few years because of the more efficient treatment of younger patients. Also, the decline in hospital mortality indicates that health care may have become more effective. Most operations carried out on senior patients are now aimed at improving the quality of life rather than lengthening it. Governmental measures to control the costs of health care have been accepted, so far, by health care providers. □

The Hazards of Extremely Low Frequency Radiation

The biological effects of extremely low frequency radiation (ELF) are unclear but "prudent avoidance" of exposure to electromagnetic radiation is advised, according to the American Industrial Hygiene Association (AIHA).

ELF, defined as radiation of 50 to 60 Hz from electric and magnetic fields, comes from appliances, wall wiring, ground currents, and service distribution lines—anything that produces electrical current. Electromagnetic radiation consists of electric radiation and magnetic radiation, but the magnetic radiation is considered to be the source of potential adverse effects.

The Environmental Protection Agency (EPA) has said that it can no longer categorically state that there is no effect from this radiation. Growing public concern about reported leukemia risk (especially in children), a possible connection with brain cancer, and potential interference with pacemakers has raised serious questions about the carcinogenicity of electromagnetic radiation.

According to ELF expert Otto White, CIH (Brookhave National Laboratory), former board coordinator to AIHA's Nonionizing Radiation Committee, several methods can mitigate ELF radiation effects. Appliance shielding, either with aluminum foil or more costly special alloys, can "attenuate magnetic fields" and limit exposures, White stated. Cancellation circuits, in which parallel systems of electric current cancel each other's effects, can also be used.

Romex cable and metal conduits can be used to prevent radiation from penetrating into the atmosphere from wiring. These methods "shield emissions so they don't go outside the device," White said. Grounding connections within a home or building can inadvertently create radiation emission zones. The proper design of grounding systems can eliminate this source, White noted.

Siting guidelines involving the locations of power lines, buildings, and residences are being increasingly examined to determine whether better locations can prevent exposures.

AIHA is a society of professionals dedicated to the health and safety of workers and the community. With more than 9000 members, AIHA is the largest international association serving occupational and environmental health professionals practicing industrial hygiene in private industry, academia, government, labor, and independent organizations.

Dogs as Sentinels for Lyme Disease in Massachusetts

Joann M. Lindenmayer, DVM, MPH, Durwood Marshall, BS, and Andrew B. Onderdonk, PhD

ABSTRACT

Background. An investigation of the relationship between incident human cases of Lyme disease and seroprevalence of antibodies to *B. burgdorferi* in dogs was undertaken in order to determine whether dogs might serve as sentinels for Lyme disease.

Methods. 3011 canine serum samples were analyzed by ELISA for antibody to *B. burgdorferi*. Records of incident human cases of Lyme disease were obtained from the Massachusetts Department of Public Health.

Results. Regression analyses of the relationship between the $\log_{10}$ (mean incidence in people 1985–1989) and canine seroprevalence from July 1988–August 1989 revealed that canine seroprevalence was highly predictive of incidence (R^2 = 0.86, $p < .0001$). A logistic regression model that incorporates the altitude of the town where each dog was resident, the date of sampling, and information on each dog's age, sex, and breed adequately explained the risk of canine seropositivity. Dogs resident at altitudes less than 200 feet, of sporting or large mixed breeds, and greater than two years of age were five times, four times, and almost three times more likely, respectively, to exhibit seropositivity than were other dogs.

Conclusions. Estimates of the prevalence of antibody to *B. burgdorferi* in dog populations offers a sensitive, reliable, and convenient measure of the potential risk to people of *B. burgdorferi* in the environment. Risk factors for canine seropositivity may directly or indirectly illuminate certain aspects of the epidemiology of human Lyme disease. (*Am J Public Health.* 1991;81:1448–1455)

Introduction

Summary statistics of incident human cases collected by the Centers for Disease Control and state departments of public health have been used to highlight national and regional distributions and changes in Lyme disease epidemiology.[1–3] Passive surveillance systems, however, are well known for underestimating actual cases of any disease. The implementation of measures designed to minimize human exposure to ticks and a geographically variable index of suspicion for Lyme disease may affect numbers of case reports, but they have little to do with changes in the environmental burden of *B. burgdorferi*.

Testing dog populations for the presence of antibody to *B. burgdorferi* has been used as an epidemiologic tool to supplement surveillance based on passive case reporting.[4–10] Dogs in endemic areas have been shown to be almost six times as likely as people to be exposed to infected ticks,[11] making them a sensitive indicator of the presence of *B. burgdorferi*. The present study was undertaken to determine whether a relationship exists between seroprevalence of antibodies to *B. burgdorferi* in the dog population and incident cases of human Lyme disease in Massachusetts. If so, dogs might serve as sentinel animals for Lyme disease.

Methods

Canine sera

Thirty-two veterinary practices located in eight Massachusetts counties participated in this study (Figure 1). Practices were chosen on the basis of the following criteria: routine use of Tufts Veterinary Diagnostic Laboratory (TVDL), willingness to participate in the study for the period of 1 year, and location. Practices were chosen to represent counties that were known, based on Massachusetts Department of Public Health records, to be endemic for Lyme disease (Dukes, Nantucket, Essex, Barnstable, and Plymouth counties), to represent areas where Lyme disease activity has recently been reported (Hampshire and Hampden counties), or to be located in areas where Lyme disease had not previously been reported (Worcester).

At each veterinary practice, veterinarians were asked to choose a convenient day of the week, and on that day to take serum samples from the first 5 to 10 consecutive dogs that were seen, regardless of the reason for presentation. If a client did not permit blood to be drawn, the veterinarian skipped that dog and continued to sample consecutively until the predetermined number of samples had been collected. For each dog sampled, veterinarians filled out brief forms providing information on the dog's breed, age, sex, owner's name and address, reason for presentation to the veterinarian, date the sample was obtained, and whether or not the dog was a Lyme disease suspect.

Sampling was undertaken from August 1, 1988, through December 31, 1988,

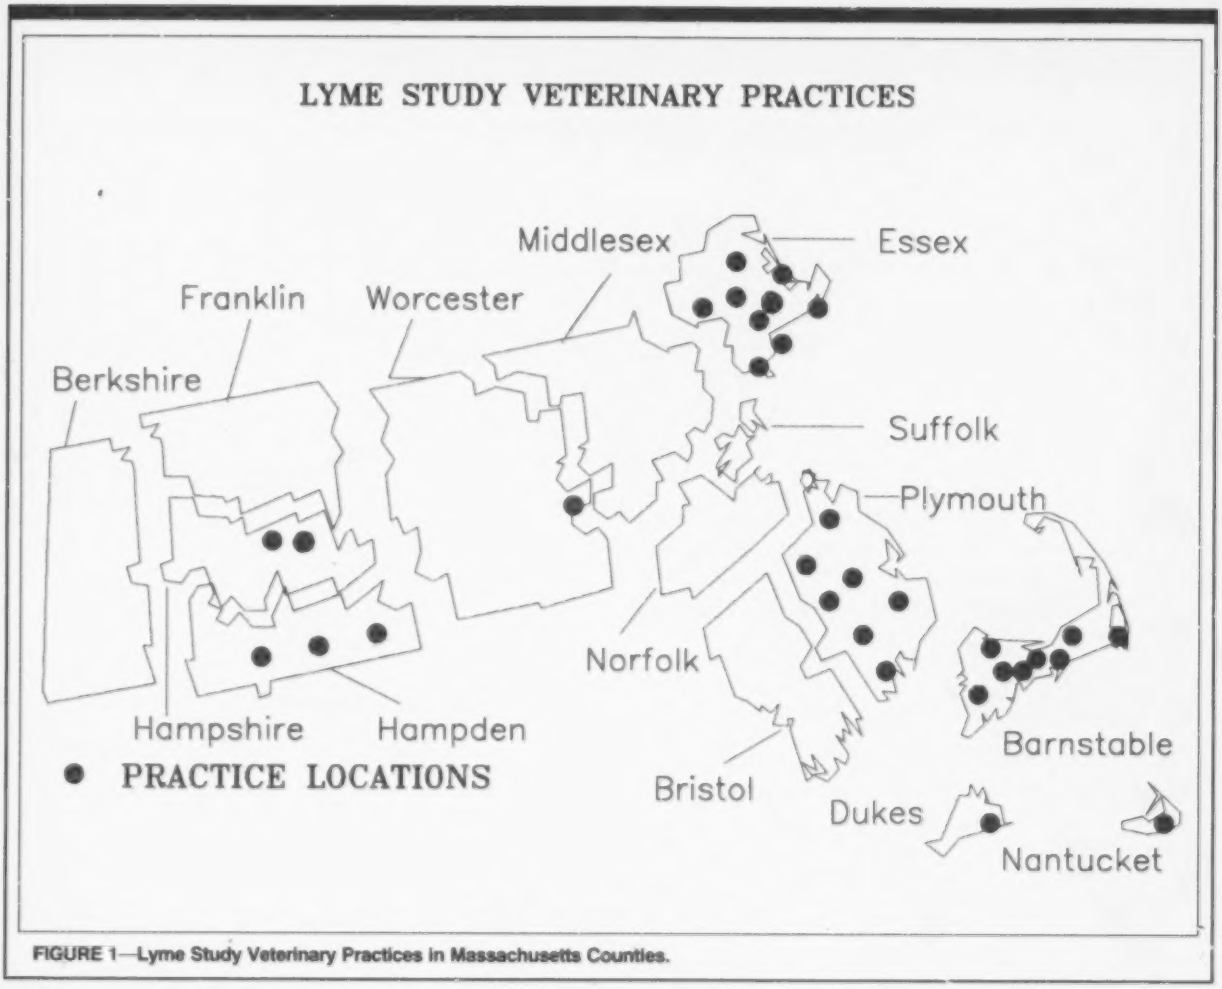

FIGURE 1—Lyme Study Veterinary Practices in Massachusetts Counties.

suspended for the winter, begun again on April 1, 1989, and continued through July 31, 1989. Samples were collected in serum separator tubes and sent to the TVDL where they were centrifuged and frozen at minus 20°C until testing could be performed. Serum samples from dogs suspected of having Lyme disease were tested within 7 days of arrival, and serum samples from dogs not suspected of having Lyme disease were tested within 4 months of arrival at TVDL. The presence of antibodies to *B. burgdorferi* was measured using an enzyme-linked immunosorbent assay (ELISA) as previously described.[12] The cutoff value for seropositivity of 0.170 optical density units is 3 standard deviations (SDs) above the mean optical density for serum samples taken from 34 apparently healthy dogs resident in areas not endemic for Lyme disease.

Human Lyme Disease Cases

Statistics on Lyme disease cases for the years 1985 to 1989 were obtained from the Surveillance Service of the Division of Epidemiology in the Massachusetts Department of Public Health.

Statistical Analysis

Canine seroprevalence was calculated as the number of dogs seropositive divided by the number of dogs tested for each category of interest. A logistic regression model was developed to estimate relative risks for canine exposure associated with five factors that were suspected, a priori, of being predictive of seropositivity.

1. *Altitude of the town where each dog was resident.* Several environmental factors have been proposed to explain the range of *Ixodes dammini*.[13-16] The distribution of incident cases of human Lyme disease in Massachusetts suggests an association between altitude, either directly or as a proxy for other factors, and incidence. Altitude was modeled on two levels depending on whether a town was located at <200 feet or ≥ 200 feet above sea level.

2. *Date the sample was drawn.* Nymphal ticks, the developmental stage most responsible for transmission of *B. burgdorferi* to people, have been demonstrated to be most active in late spring and early summer, whereas adult ticks have been most active in the fall and winter.[17] The sampling date was thus modeled on two levels, depending on whether a sample was obtained between August 1 and December 31, 1988, or between April 1 and July 31, 1989. These dates roughly correspond to fall/winter and spring/summer seasons.

3. *Sex.* This factor was modeled on two levels, male and female, regardless of whether a dog was intact or neutered/spayed. Previous studies indicate that male dogs may be predisposed to exposure to *B. burgdorferi*.[9]

4. *Breed.* Three levels of breed were chosen to reflect the relative probability of

exposure to ticks in the environment—sporting and large mixed breed dogs (high probability of exposure), toy and small mixed breed dogs (low probability of exposure), and all others, including working, hound, terrier, nonsporting, medium mixed breeds, and dogs of unknown breed status (intermediate probability of exposure).

5. *Age of the dog at the time of sampling.* The risk for dogs of testing positive for antibody to *B. burgdorferi* has been found to be associated with the cumulative time of *I. dammini* exposure,[11] although other studies have reported a greater degree of seropositivity and higher antibody titers among younger than among older dogs.[6,9] Age of dogs, as a proxy for cumulative time of exposure, was modeled on two levels, ≤2 years of age and >2 years of age.

Logistic regression analyses were carried out with BMDP and SAS, and Pearson χ^2 analysis was performed with StatXact (Cytel Software Corporation, Cambridge, Mass).

Results

Characteristics of the Study Population

During the period August 1, 1988, to July 31, 1989, 3011 serum samples obtained from 2941 Massachusetts dogs were tested for the presence of antibody to *B. burgdorferi.* Seventy dogs, or 2% of the total population, were sampled twice, the second time for reasons unrelated to the present study. Males and females were approximately equally represented (46.4% vs 49.5%, respectively). Sex of the remaining 4.1% of the study population was not noted by veterinarians. Sporting, large mixed breed, and working dogs comprised the majority of the breeds represented (29.4%, 24.3%, and 19.6%, respectively). All other breeds were approximately equally well represented. The percentage of dogs in each age category ranged between 5.7% and 8.9% up to 11 years of age. Above that, the percentage in each age category ranged between 0.1% (>15 years old) and 4.7%.

Seroprevalence

Among all dogs tested, unconditional seroprevalence was 20.3%.

Comparison of incidence and prevalence. Canine seroprevalence was calculated by dogs' place of residence, the most likely site of exposure to *B. burgdorferi.* This permitted inclusion of 262 of 351 Massachusetts communities in the analysis.

Great variation exists among incident human cases by county from year to year (Table 1). By contrast, canine seroprevalence data were available for every county in the state except one, and, because so many dogs were sampled, reasonable confidence intervals could be calculated for each point prevalence estimate. A comparison of incidence and prevalence by town for a single county (Essex) likewise confirms the completeness and stability of the canine data (Table 2).

Regression analyses of the relationship between canine seroprevalence in 1988 to 1989 and human incidence per 100 000 persons for each year between 1985 and 1989 by county were unable to statistically confirm the utility of canine seroprevalence as a predictor of the number of human cases. This is likely attributable to the small number of documented county-specific cases in any given year. In order to overcome the variability inherent in the human data, cases of Lyme disease were averaged by county for the years 1985 through 1989. When the relationship between $\log_{10}$ (mean incidence in humans 1985–1989) and canine seroprevalence was explored, canine seroprevalence was found to be highly predictive of incidence ($R^2 = 0.80$, $P < .0001$) (Figure 2).

Seroprevalence by month. Seroprevalence by month of sample submission did not vary with the exception of November 1988, when a particularly high proportion of samples exhibited seropositivity (Figure 3).

Note. — = no cases reported/no dogs tested.
[a] Cases per 100 000 persons (Source: Massachusetts Department of Public Health).
[b] Number seropositive/number tested × 100.
[c] CI = confidence interval.
[d] Represents a single case.
[e] Represents testing of ≥5 dogs.

Seroprevalence by breed. Seropositivity was highest among sporting and large mixed breed dogs and lowest among toy and small mixed breed dogs (Figure 4).

Seroprevalence by age. Degree of seropositivity was lowest among dogs ≤2 years of age. Above 2 years of age, seropositivity remained relatively stable (Figure 5).

Sensitivity of the Canine Model

Using seropositivity alone, far more dogs tested positive for exposure to *B. burgdorferi* than incident human cases were reported. Comparing mean incidence for 1985 to 1989 with canine seroprevalence by county, seropositivity estimates were 513 to 17 857 times greater than incident human cases.

Veterinary suspicion for Lyme disease was associated with serologic test results. Of 203 dogs that were noted to be Lyme disease suspects based on clinical presentation, 91 (44.8%) tested positive for exposure to *B. burgdorferi*, whereas only 18.4% (465/2530) of nonsuspects and 20.1% (56/278) of dogs whose Lyme disease status was not noted tested positive for exposure. The Pearson χ^2 test statistic was 141.7 (df = 2, P = .0011) and was based on a Monte Carlo simulation of 2000 tables generated from fixed marginal distributions of the observed data.

Logistic regression. Of the dogs studied, 2789 met the criteria that comprise the population profiles for the logistic regression model and were included in the analysis. The standard logistic regression model had the following form:

$$\ln(p/1-p) = -4.74 + 1.64T - 0.20D - 0.05S + 0.82B1 + 1.41B2 + 1.03A,$$

where

- p = probability of testing positive
- 1−p = probability of testing negative
- T = altitude of town where dog was resident
- D = season serum sample was obtained
- S = sex of dog
- B1 = indicator variable for the differential effect of moderate vs low exposure by breed
- B2 = indicator variable for the differential effect of high vs low exposure by breed

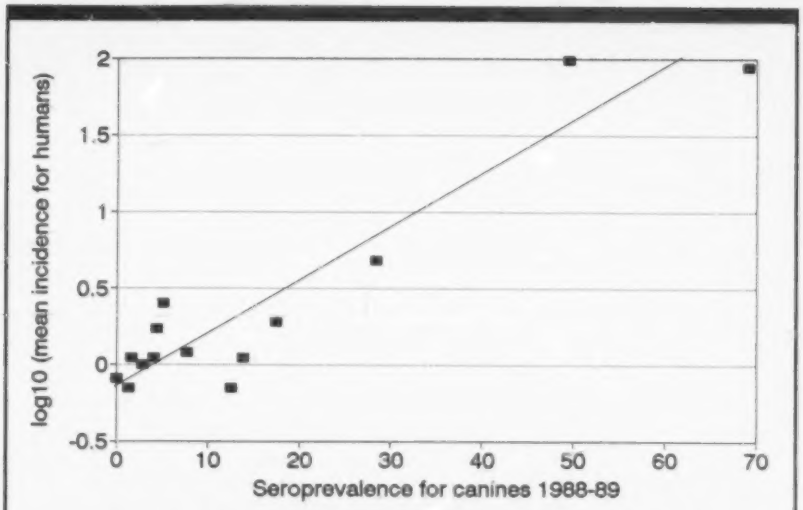

FIGURE 2—Least-Squares Regression Line for $\log_{10}$ Mean Intercept = 0.13, Slope = 0.03, Adjusted R^2 = 0.86 (P <.001). Human Incidence 1985–89 vs Canine Seroprevalence, for 13/14 Massachusetts Counties.

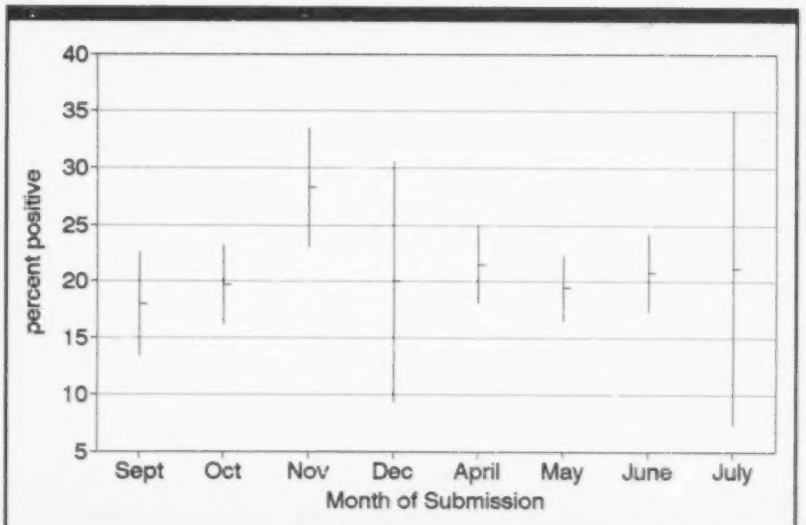

FIGURE 3—Canine Seroprevalence by Month (mean ± 95% confidence interval).

A = age of dog at time of sampling

The χ^2 goodness-of-fit statistic for the equation sum[2 $O_i \times \ln(O_i/E_i)$] was 34.37 (df = 39, P = .68), suggesting that the model adequately explained the test outcome. The 48 possible cells resulting from the coding of the five factors yielded two cells without any observed data due to incomplete records. Two of the 46 remaining cells proved to be particularly unusual and not well accommodated by the logistic model. These two cells were low-exposure breed female dogs <2 years of age, resident at low altitudes and sampled in the spring or summer (n = 3), and low-exposure breed male dogs ≥2 years of age, resident at high altitudes and sampled in the fall or winter (n = 5). These cells, because of their small counts, are unlikely to be representative of the corresponding population profiles. For this reason, they were removed from the analysis. The recalculated χ^2 goodness-of-fit statistic was 29.84 (df = 37, P = .825). All final results are based on the latter model.

Odds ratios for factors included in the model (Table 3) revealed that dogs resident at or near sea level were approximately five times as likely to test positive for exposure as dogs resident at higher elevations. Breeds with moderate probability of exposure and those with high probability of exposure were more than two times and more than four times as likely, respectively, to test positive than breeds with low probability of exposure. Linear contrast analysis for differences between breeds with high probability of exposure and all others indicated that the former were far more likely to be exposed than the latter (χ^2 = 33.01, P = .0001). Dogs >2 years of age were almost three times as likely to test positive as dogs ≤2 years of age. Dogs sampled in the spring or summer were slightly less likely than dogs sampled in the fall or winter to test positive, although this difference was not significant. Sex of the dog had no effect on the probability of testing positive.

TABLE 3—Odds Ratios (OR) for Logistic Regression Factors

Factor	OR(95% CI[a])
Intercept	0.01 (0.00–0.02)
Altitude	5.15 (3.37–7.87)
Date	0.82 (0.67–1.00)
Sex	0.96 (0.79–1.15)
Breed1[b]	2.28 (1.23–4.23)
Breed2[c]	4.10 (2.23–7.51)
Age	2.80 (2.01–3.91)

[a]CI = confidence interval
[b]Breeds with moderate probability of exposure.
[c]Breeds with high probability of exposure.

In the logistic regression model, cells with the highest probabilities for seropositivity (>0.22) represented dogs that lived at altitudes <200 feet, of the sporting or large mixed breed types, and older than 2 years of age. No differences with respect to date of sampling or sex were noted. Cells with the lowest probabilities for seropositivity (<0.017) represented dogs that lived at altitudes ≥200 feet, were <2 years of age, and were of low and moderately exposed breed types. As before, no differences in date of sampling or in sex were noted.

Discussion

The dog has been proposed for use as a sentinel animal to detect the presence of *B. burgdorferi* for two reasons. Dogs exposed to infected ticks develop antibodies to the spirochete and often exhibit clinical signs of the disease similar to those in people. Second, dogs are more likely to be exposed to infected ticks because they come into more physical contact with tick habitats than do most people, and because

measures to prevent exposure to ticks are difficult to implement in dogs. Results of the present study indicate that under certain conditions canine seroprevalence estimates are highly predictive of incident human cases, further strengthening the usefulness of dogs as sentinel animals.

The present comparison between two different measures of disease and two different time periods is unavoidable for two reasons. Incident canine cases of Lyme disease are difficult to determine. Efforts to induce seroconversion to *B. burgdorferi* or clinical Lyme disease in laboratory dogs have not been uniformly successful.[18,19] Furthermore, dogs often exhibit seropositivity to the spirochete without concomitant clinical evidence of disease.[6-8,11,18-21] It is unlikely, then, that incident cases among dogs will ever be available for comparison with human incidence rates. Second, regression analyses of canine seroprevalence in 1988–1989 and human incidence for each year between 1985 and 1989 failed to reveal a relationship between the two. This is probably due to the great variability inherent in incident human cases from year to year. Seroprevalence estimates among dogs for a given year are likely to be stable because so many dogs can be sampled under an active surveillance system. It would, however, be useful to extend these studies over a longer period of time in order to determine whether or not these observations are maintained.

The overall seroprevalence estimate of 20.3% for this study does not reflect seroprevalence among all Massachusetts dogs because participating veterinary clinics were chosen to afford maximal coverage of particular counties in Massachusetts. For this reason, county- and town-specific seroprevalence rates are more likely than state-wide estimates to be representative of dogs presented for veterinary care in these regions. However, all seroprevalence estimates may actually underestimate true seroprevalence because they were based on dogs presented to veterinary practices rather than the general canine population. Inclusion of stray dogs and dogs that do not receive regular veterinary care might well increase seroprevalence estimates because these dogs would be more likely to run free and therefore be exposed to infected ticks.

Seroprevalence estimates were based on the assumption that seropositive dogs received exposure in the towns where they resided. In fact, dogs often travel with their owners, particularly in the summer months. This raises the possibility that individual seropositive dogs were exposed to infected ticks at locations other than their towns of residence and might account for the presence of seropositive dogs in towns where Lyme disease is not known to be endemic.

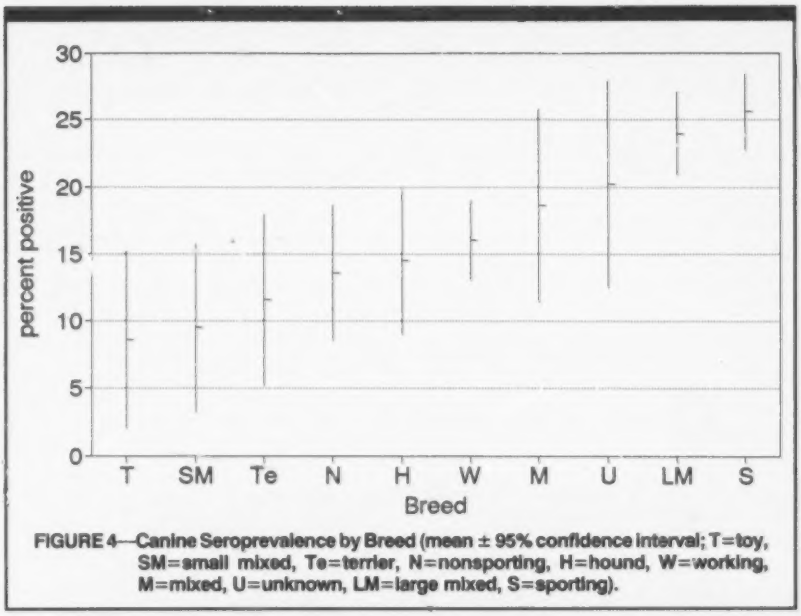

FIGURE 4—Canine Seroprevalence by Breed (mean ± 95% confidence interval; T=toy, SM=small mixed, Te=terrier, N=nonsporting, H=hound, W=working, M=mixed, U=unknown, LM=large mixed, S=sporting).

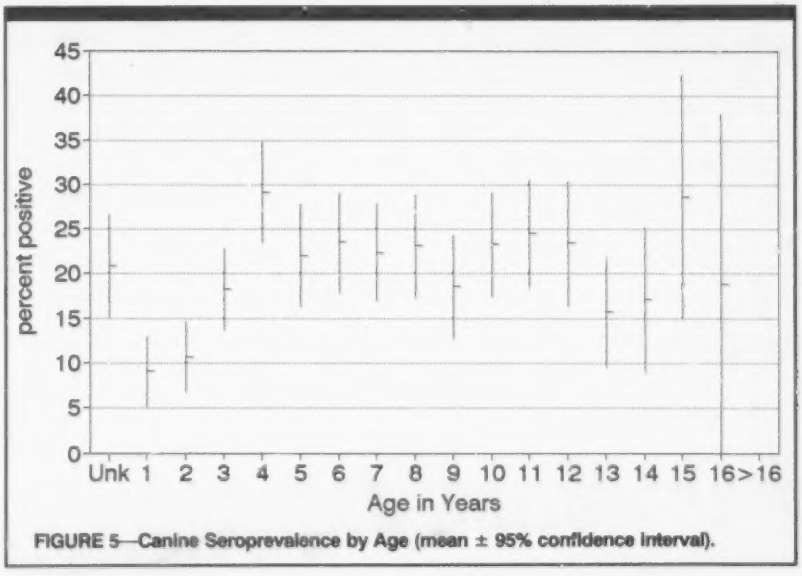

FIGURE 5—Canine Seroprevalence by Age (mean ± 95% confidence interval).

Previous studies in this laboratory and elsewhere[12,22-24] have documented false positive ELISA test results for both canine and human serum samples. While we recognize that this possibility exists, test results from an area where Lyme disease is not known to be endemic by Massachusetts Department of Public Health standards (i.e., Worcester County) indicate that a very small proportion of dogs (1/78 or 1.3%) tested positive for antibody to *B. burgdorferi*, presumptive evidence that the proportion of false positive samples in this study is low.

Use of the canine to detect and quantify Lyme disease risk offers several advantages over the use of human incidence rates alone. Dog populations are particularly convenient to test for exposure to *B. burgdorferi*. Dogs are routinely brought to veterinarians in the spring for heartworm testing. Blood drawn for this purpose can likewise be made available for Lyme disease testing, obviating the need for a separate visit to the veterinarian. Furthermore, dogs tested at this time of year are

usually well animals presented for routine checkups and are thus more likely than dogs presented at other times of the year to be representative of veterinary clinic catchment populations.

Second, seroprevalence estimates in dogs not only reflect incidence rates in people, but they also appear to be a far more sensitive indicator of the presence of *B. burgdorferi* than do the latter. Seropositivity for every 100 000 dogs tested was consistently much higher than Lyme disease incidence per 100 000 persons.

Third, seroprevalence estimates in dogs are more likely to reflect the actual environmental risk of Lyme disease than are reports of incident human cases. Factors such as increasing awareness of Lyme disease may falsely increase incidence rates, whereas the use of measures to prevent exposure to ticks may actually decrease incidence rates apart from any changes in the environmental burden of *B. burgdorferi*. Measures designed to prevent dogs from exposure to potentially infected ticks are frequently unrewarding. Dogs' propensity to pick up large numbers of ticks and the difficulties associated with finding tiny *I. dammini* make tick exposure a near-certainty in endemic areas except, perhaps, for dogs that rarely venture outdoors.

Fourth, canine seroprevalence estimates permit a fairly complete representation of areas of potential risk to be drawn. As evidenced by the Massachusetts Department of Public Health data, collected under a passive reporting system, incidence measures for a particular county or town are frequently based on a single case report. Furthermore, marked year-to-year variability in incidence rates is frequently observed. Under an active canine surveillance system such as the one used here, additional information was made available to permit the calculation of point prevalence estimates and reasonable confidence intervals for 31 of 34 towns in one particular county (Essex) and for 13 of 14 counties.

The logistic model employed in the present study appears to adequately explain the risk of seropositivity among Massachusetts dogs and has defined certain risk factors for canine exposure, namely, altitude of town of residence, breed of dog, and age. Dogs that live at altitudes <200 feet above sea level appear to be at greater risk for exposure to *B. burgdorferi*. The fact that seroprevalence varies widely even at this altitude raises the possibility that ecologic factors such as humidity or temperature may affect deer tick survival and thus the risk of exposure to Lyme disease. Lyme disease is also known to occur in noncoastal areas of the United States where altitude may not be definable as in the present model.

Previous studies have not been able to confirm a breed disposition among seropositive dogs, although mixed breed dogs and hunting breeds were more frequently seropositive.[9] The present study, perhaps because of a larger sample size, establishes that seropositive dogs are more likely to be sporting and large mixed breed dogs. These animals are presumably at greater risk of exposure because the former are used for hunting and sporting purposes and the latter, by virtue of their size, may be allowed more freedom to roam.

Dogs >2 years of age appear to be at greater risk of exposure than younger dogs. Other studies have documented maintenance of antibody titers in dogs months to years after initial exposure to the spirochete.[20,21] Under these circumstances, seroprevalence could be expected to increase with advancing age. In the present study, however, age-specific seroprevalence estimates appear relatively stable above 2 years of age. It may be that, for a given dog population, only a fixed proportion of its members are at risk for exposure to *B. burgdorferi*. For example, a smaller proportion of dogs might be at risk in areas with large urban populations and strict leash laws than in rural areas with less restrictive leash laws. Dogs at risk may be exposed to infected *I. dammini* and seroconvert at an early age, and thus, after the critical age of 2 years, no increase in age-specific seropositivity would be noted.

In the present study, sex appeared not to explain seropositivity. Information on reproductive status of an animal, whether intact or neutered/spayed, was requested but frequently not provided. It is possible that reproductive status, as an indicator for proclivity to roam, might well be a risk factor for seropositivity, although this could not be determined in the present study.

The risk factors identified for dogs may directly or indirectly illuminate certain aspects of the epidemiology of human Lyme disease. Altitude can certainly be a risk factor for people. Age, as a proxy for cumulative duration of exposure, and breed, as a proxy for occupational or recreational exposure, are other factors that should be considered in models investigating the risk of Lyme disease in people.

A vaccine against *B. burgdorferi* has recently been made available for use in dogs (Borrelia burgdorferi Bacterin, Fort Dodge Laboratories, Fort Dodge, Iowa). Widespread use of such a vaccine could well compromise the ability of canine populations to serve as sentinel animals for Lyme disease. Vaccinated dogs would presumably be protected against field exposure to the spirochete and antibody titers in vaccinated dogs would be indistinguishable from those of naturally exposed dogs. The degree to which the dog-owning public avails itself or the vaccine remains to be seen. However, the vaccine is likely to be put to greatest use in Lyme disease–endemic areas where a sentinel system would be of least benefit. Dogs in nonendemic areas might well still serve as an early warning system for detection of the spirochete if they remain largely unvaccinated. □

Acknowledgments

This work was supported by a public health fellowship from the Massachusetts Health Research Institute of the Medical Foundation, Boston, Mass, to Dr. Lindenmayer.

The authors are grateful to the veterinarians who participated in this study, and in particular to Dr. Frederick Johnson, Dennis Animal Hospital, Dennis, and Drs. James Dasbach and John Rae, Nantucket Animal Hospital, Nantucket, Massachusetts, for their many helpful comments and suggestions. Mr. Paul Etkind, Director, Epidemiology Program of the Massachusetts Department of Public Health, critically reviewed the manuscript.

APHA's Food and Nutrition Section Announces Awards

The Food and Nutrition Section of the American Public Health Association announces the availability of the Helen R. Stacey and Joseph A. Walsh awards for graduate education at the master's degree level in public health nutrition. Three awards are given consisting of $2000 each. These awards must be used for the academic year 1992 to 1993. Applications must be submitted no later than May 1, 1992.

Nominations are being solicited for the Mary C. Egan Award for Outstanding Professional Contributions and Service in Public Health Nutrition. This award carries with it a $1000 honorarium. Nominations must be submitted no later than May 1, 1992.

Applications and nominations forms may be secured from Elvira Jarka, MS, RD, Chair, Awards Committee, F&NS, APHA, Lake County Health Department, 2303 Dodge, Waukegan, IL 60085.

National Health Objectives for the Year 2000: The Demographic Impact of Health Promotion and Disease Prevention

ABSTRACT

Background. The national objectives in *Healthy People 2000*, drafted by health professionals aware of currently available public health interventions, represent a wealth of information about near-term future mortality and morbidity.

Methods. Life table methods were used to calculate the impact of projected changes in mortality and activity limitation rates on life expectancy and expected disability years.

Results. Meeting the mortality objectives would increase life expectancy at birth by 1.5 to 2.1 years, raising life expectancy to 76.6 to 77.2 years. In addition, meeting the target for disability from chronic conditions would increase the number of years of life without activity limitations from 66.8 years to 69.3–69.7 years. If the targets for coronary heart disease and unintentional injury were changed to reflect recent trends, a greater improvement in life expectancy at birth would be achieved: from 1.8 to 2.7 years to 76.9 to 77.8 years.

Conclusion. Meeting the targets would have an important demographic impact. Including changes in the coronary heart disease and injuries targets, life expectancy in the year 2000 would be above the middle of the ranges used in current Census Bureau projections. Introduction

On September 6, 1990, the US Public Health Service (PHS) released *Healthy People 2000: National Health Promotion and Disease Prevention Objectives,*[1] a report on some 300 national health objectives for the year 2000. Based on the input of scientists and health professionals in many fields, PHS set specific numerical targets that are thought to be achievable over the next decade and identified data to track progress toward these targets. As experience with the earlier 1990 Objectives for the Nation[2] has shown, tracking these objectives can help to identify areas of success as well as areas that need more attention and resources. Thus the objectives will help guide health policy over the next decade.

The objectives are organized into 22 "priority areas" relating to specific problems, conditions, or diseases; risk factors; or potential interventions (see Table 1). Each priority area presents objectives for particular health status measures, for reduction of risk factors, and for provision of health services and protective measures. In total, the report contains about 300 objectives for the general population plus more for minority groups and other populations of special concern.

The objectives bring to bear in a specific and quantitative way the informed judgment of public health experts on a critical demographic issue, future improvements in mortality and morbidity. The objectives were developed by groups of scientists and public health professionals who are aware of the currently available and soon-to-be available public health interventions. Therefore, they represent a wealth of information about both future mortality and morbidity in the United States and the potential for health promotion and disease prevention interventions.

The objectives were, however, written by many independent committees and appear in a number of different formats. Some objectives target improvements in specific causes of mortality and morbidity but use noncomparable or nonstandard measures to provide a baseline. Other objectives specify potential changes in risk factors, use of preventive services, and other implementation strategies, and they are not directly translated into mortality or morbidity measures.

The intent of this paper is to organize and analyze in demographic terms the potential for future reductions in mortality and morbidity implicit in the national objectives. Specifically, we calculate the impact on life expectancy and other summary demographic measures of meeting the targets set in the objectives. This analysis serves two purposes. First, it summarizes in quantitative terms the scientific and medical knowledge of the many experts who participated in setting the objectives. This should be of interest to demographers and forecasters who want a stronger scientific backing for their future mortality and morbidity projections. Second, it offers guidance for enhancing further efforts in health promotion and disease prevention. The analysis shows where the potential for health status improvements is high and low and thus in-

forms discussions about setting priorities among the objectives.

Methods

A number of technical features of objectives development should be taken into account in trying to develop measures of the overall mortality impact of meeting the objectives.

Because the objectives were drafted by 21 different working groups, the statistical measures used lack the unity of method that they would have if they had been developed by demographers and statisticians. Among mortality measures, for instance, nonstandard cause-of-death categories, rather than the categories used in vital statistics reports[3] and *Health, United States 1989*,[4] are used for coronary heart disease, diabetes, pneumonia and influenza, and a number of specific kinds of injuries.

One of the hallmarks of the national objectives process is that it sets specific numerical targets for the future. This allows policymakers to assess progress in mid-decade and to redirect efforts in areas where we are falling behind. The groups drafting the objectives had varying approaches to setting targets, including (1) detailed demographic models of the impact of changes in risk factors and the use of preventive services on disease incidence and mortality, (2) simple and sophisticated statistical trend analyses, and (3) eyeballing the most recent data points in conjunction with educated guesswork. Because of the different methods used, some of the targets—specifically, those for coronary heart disease and unintentional injuries—look somewhat optimistic or conservative when compared to each other and to mortality trends.

The analysis in this paper focuses primarily on the mortality objectives, a small fraction of the total set of objectives. The objectives address many other health status concerns—such as the incidence or prevalence of specific diseases, disabilities, or other conditions—as well as present targets for risk factor reductions and improvements in the provision of preventive services. Because they were expressed in so many different ways, we were not able to incorporate most of the morbidity and disability measures into a common framework. We were, however, able to incorporate a single objective addressing overall activity limitation into a comprehensive measure of mortality and disability.

Demographic Framework

In order to sum up the demographic impact of achieving the mortality objectives by the year 2000, we had to translate the objectives developed by PHS into a common framework for demographic calculations. As shown in Table 2, we developed a cause-of-death list that is a compromise between the specific measures used in the objectives (and the prevention relevance that they represent) and the standard groupings from the International Classification of Diseases, Ninth Revision (ICD-9)[5] used to report vital statistics. The 1987 death rates for these causes of death serve as the base for our calculations.

Infant mortality is included in the list, even though it is not a single cause of death, because the measure appears prominently in *Healthy People 2000*[1] and is frequently cited in health policy discussions. Pneumonia and influenza are grouped in a residual category, Other Causes, for which there are no objectives or the objectives cannot be translated to appropriate death rates.

To translate the mortality measures in the objectives into a common set of cause-specific death rates, we assumed that the annual rate of change implied by comparing the baseline figure and the target applied to the change in death rates from 1987 to 2000 for standard ICD groups.

One category in Table 2, heart disease, has a residual that represents the part of the category that is not covered by the target of any specific objective, primarily because prevention efforts are thought to be significant only for the heart disease deaths due to coronary heart disease. Together the heart disease residual and the overall residual made up 10% of total deaths in 1987. For heart disease and

TABLE 2—Major Causes of Death: 1987 Age-adjusted Death Rates and Alternative Rates of Change to the Year 2000[6]

Causes of Death	1987 Death Rate[a]	Alternative Annual Rates of Change: High Mortality Trend	Low Mortality Trend	PHS Targets	Target and No Change in Residual	Target and Residual Trend
Chronic diseases						
Heart disease	169.6	−2.23	−2.37	−2.28	−1.43	−1.78
Cancer	132.9	0.13	0.06	−0.18		
Stroke	30.3	−3.04	−5.19	−3.15		
COPD[b]	18.7	3.00	0.00	2.26		
Diabetes	9.8	0.16	−2.44	−0.79		
Cirrhosis	9.1	−3.22	−3.94	−3.15		
Injuries						
Suicide	11.7	0.50	−0.32	−0.83		
Homicide	8.6	−0.98	−3.23	−1.27		
Unintentional injuries	34.6	−2.53	−2.96	−1.25		
Infant mortality	1018.5	−2.70	−4.15	−2.78		
Other causes of death						
Pneumonia and influenza	13.1	1.64	−3.44	−1.68		
All other causes	97.0	0.26	−2.11	0.00	0.00	0.26

[a]Death rates are per 100 000 population; the infant mortality rate is given per 100 000 live births.
[b]Chronic obstructive pulmonary disease.

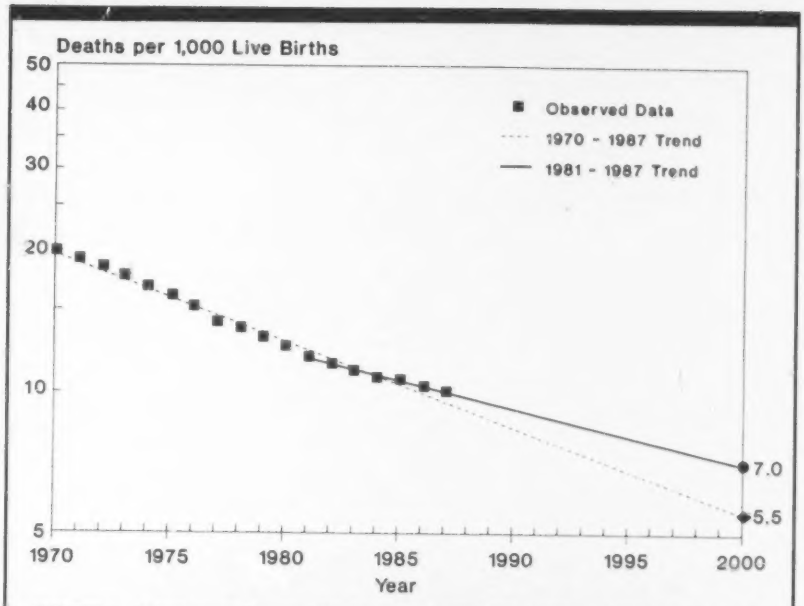

FIGURE 1—Infant mortality rate, 1970 to 1987, with 1970–1987 and 1981–1987 trends projected to the year 2000 (logarithmic scale), from *Health, United States, 1989*[4] and earlier editions of that report.

total mortality we calculated the target rate of change using three assumptions about the rate of change in the residual categories:

1. *Target:* the residual heart disease component changes at the same rate as the targeted part, and the overall residual mortality rate does not change.
2. *No change:* the residual heart disease component and the overall residual do not change.
3. *Own trend:* the residual heart disease component and the overall residual change according to the trend observed from 1979 to 1987.

Table 2 shows the three variants for the annual rate of change. The Appendix lists these and other specific assumptions made in translating the year 2000 objectives to a common demographic framework.

Trend Analyses for Comparison Purposes

To establish a reference point in a comparable manner for all of the cause-of-death categories, we chose to use simple trend analyses to estimate the potential changes in mortality that might come about even without the efforts implicit in the objectives process. More sophisticated techniques could be used here, but, given the illustrative nature of the effort, simple trend analyses are sufficient.

Because most of the rates are moving toward zero and some would become negative if linearly extrapolated to the year 2000, all of our trend analyses are in a logarithmic scale, implying a constant relative annual change. The trend analyses are based on rates for the whole population age-adjusted to the 1940 US standard million population.[4]

A look at the data going back to 1970 indicates that some trends were not simple. For example, infant mortality, as shown in Figure 1, saw a leveling off in the 1980s of the sharp downward trend experienced in the 1970s. The result is that a trend line fit to the data from 1970 to 1987 gives a very different rate of change than one fit to the data from 1981 to 1987, the years used by PHS to determine the target value for the infant mortality rate (IMR). For some other causes, the death rate is actually increasing, and the rates for other causes show substantial variability over the period.

To reflect the uncertainty in these simple trend analyses, we have developed high and low mortality variants for each cause of death. This approach assumes that the major source of uncertainty is in deciding which points to include in the trend calculation, not variation around the trend line. For most causes, the high and low variants reflect the different trend estimates calculated using data from 1970 to 1987 and data from 1979 or later to 1987. The 1970 starting point was chosen arbitrarily. The 1979 starting point corresponds to the implementation of ICD-9 in the United States, and in some cases changes between ICD-8 and ICD-9 cause major discontinuities in the data. For some causes of death PHS based the target on a trend analysis starting after 1979; for those causes we considered the additional trend line in establishing high and low mortality variants. For chronic obstructive pulmonary disease (COPD) the trend in the death rate is increasing, and we assumed a zero rate of change for the low mortality alternative. Table 2 shows the annual rate of change for the high and low mortality projections for each cause of death.

Calculation of Summary Mortality Measures

We present our results in terms of standard life table parameters e_0 (life expectancy at birth), l_{65} (the probability of surviving to age 65), and l_{65} (life expectancy at age 65). Further calculations suggest that the major qualitative conclusions regarding mortality are seen in these measures alone. The calculations were done as follows.

We started with the age- and cause-specific rates for 1987,[6] using the following age ranges: 0, 1, 5(10)85. For each cause we then applied the relative annual rate of change from Table 2 to each 1987 age-specific rate for that cause to calculate cause-specific death rates for the year 2000. For infant mortality we assumed that the targeted rate of change for IMR applied to ${}_1q_0$. We did not take cause-specific mortality rates into account in calculating ${}_1q_0$.

These cause-specific rates were aggregated into age-specific ${}_nM_x$ rates, and transformed into life table ${}_nq_x$ rates using Chiang's a's,[7] modified for 10-year intervals. Although these abridged calculations are not exact, if we assume no change for every cause, we can reconstruct the 1987 life table parameters[6] without excessive error. For instance, the actual and calculated values for e_0, e_{65}, and l_{65} are as follows:

Parameter	Actual	Calculated
e_0	75.0	75.1
l_{65}	16.9	17.2
l_{65}	79 040	79 139

Because most of the objectives are stated in terms of total population rates, we have not attempted to differentiate targets or trends in age, race, or sex-specific

rates. All of the rates of change in Table 2 are for the total population.

In order to consolidate these calculations on the impact of changes in mortality with a targeted reduction in disability, we adapted methodology developed by Sullivan[8] and used by others[9,10] that allows us to estimate an expectation of life free of disability. The measure of disability that we use is drawn from Objective 17.2 in *Healthy People 2000*,[1] which calls for a decline in the proportion of the population with major activity limitations from 9.4% in 1988 to 8.0% in 2000, a decrease of 1.34% per year. The baseline data come from the National Health Interview Survey (NHIS), which provides estimates of the proportion of the civilian noninstitutionalized population that experiences a limitation in their "major activity" due to a chronic health condition.[11] Major activity is defined as the predominant social role expected of a person of a given age: playing for children under age 5, attending school for children aged 5 to 17, working or keeping house for adults aged 18 to 69, and living independently for adults aged 70 and older.

We assumed that the 1.34 annual percentage decline between the baseline and the target would apply in each of the age groups in which the NHIS data are tabulated. For the base year and 2000, we calculated the number of life table years lived with major activity limitation by multiplying the prevalence of major activity limitation in each age group by the number of life table years lived in that age group ($_nL_x$) and summing the products for age x and above. The result can be expressed as the life expectancy with major activity limitation. Subtracting that value from total life expectancy gives an estimate of expected years of life free of limitation in major activity. Because the NHIS figures exclude the institutionalized population, including residents of nursing homes and other long-term care facilities, our calculations underestimate time with activity limitations.

Results

We have calculated the effect of meeting the objectives on overall mortality and on life expectancy without limitation in major activity, examined the impact of meeting specific objectives and groups of objectives on overall mortality and on the distribution of causes of death, and carried out an in-depth exploration of the specific targets chosen for coronary heart disease and unintentional injuries.

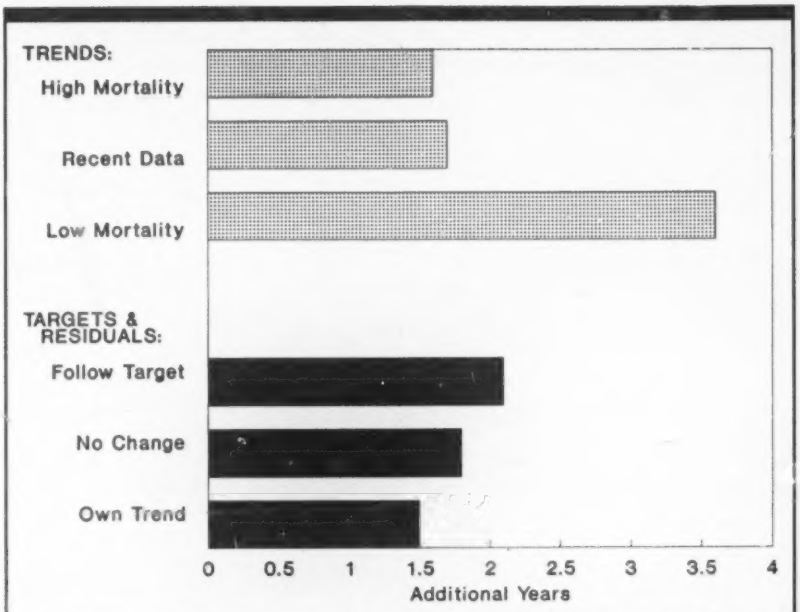

FIGURE 2—Projected increases in life expectancy at birth from trend and target changes in mortality from all causes: 1987–2000.

Overall Mortality

The effect of meeting the mortality objectives on overall life expectancy is shown in Figure 2. Depending on which of the two trend variants is used, the increase in life expectancy at birth by the year 2000 can range from 1.6 to 3.6 years. Although the trends based on data from the 1980s are not the least optimistic for every cause of death, they are in most cases. If trends based only on the more recent data were assumed, the increase in life expectancy at birth by the year 2000 would be about 1.7 years. Figure 2 also shows that the increase in life expectancy at birth to be expected if the *Healthy People 2000*[1] objectives are met is from 1.5 (assuming trends for the nontargeted causes of death) to 2.1 years (if residual rates improve at the same rate as the targeted rates). These figures imply a life expectancy of 76.6 to 77.2 years. Life expectancy at age 65 increases by 1.0 to 2.5 years with trends alone, and by 1.0 to 1.4 years if the year 2000 objectives are achieved. The current life expectancy at age 65 is 17.2 years.

Similarly, the increase in l_{65}, the life table probability of living to age 65, increases by 1.9 to 3.7 percentage points according to the two trend variants, but from 1.8 to 2.3 points if the year 2000 objectives are achieved. Thus, meeting the mortality targets would increase the probability of surviving to age 65 from 79.1% to 80.9–81.5%. Alternatively, one could say that the probability of a "premature death" would decrease from 20.9% to 18.5–19.1%. For all three measures, the targets are closer to the low end of the range defined by the alternative trends than the high end of the range.

Years without Limitations in Major Activity

With current mortality and disability statistics, an average of 66.8 years out of 75.1—89% of life expectancy at birth—would be spent free of limitation in major activity. If the target rate for major activity limitation is achieved, however, the number of years without limitation will increase to 69.3 to 69.7 years—approximately 90% of total life expectancy—depending on the assumption about trends in nontargeted causes of death as above. The scenario that produces the largest increase in total life expectancy also produces the largest increase in disability-free life. That same scenario, however, also results in the greatest remaining number of years with activity limitation (7.5 years) because relatively more people survive to the older ages at which disability is most prevalent.

Under current conditions, an average of 13.2 disability-free years would be experienced after age 65—about 77% of the life expectancy at that age. Assuming that the year 2000 objectives are met, the number of disability-free years experienced af-

TABLE 3—Estimated Impact on e_0 and l_{65} of Projected and Targeted Changes in Death Rates for Individual and Grouped Causes of Death: Year 2000

Causes of Death	Projected Changes		Targeted Changes		
	High Mortality Trend	Low Mortality Trend	PHS Targets	Target and No Change in Residual	Target and Residual Trend
Added years of life expected at birth (e_0)

[a]Chronic obstructive pulmonary disease.

ter age 65 increases to 14.6–15.0 years—about 80% of the life expectancy at that age.

Changes in Specific Causes of Death

To understand these results better we need to explore the contributions of specific causes and groups of causes to these summary measures. Table 3 shows the effect on e_0 of trend and target changes for each cause of death, assuming no changes in mortality for other causes. The potential changes in heart disease will have the largest impact on the increase in life expectancy (0.8 to 1.2 years), followed by stroke (0.3 to 0.4 years) and infant mortality (0.2 to 0.3 years). This should be compared to a range of 1.5 to 3.6 years of potential increase in overall e_0. Cancer mortality trends are increasing slightly, and the effect of meeting the target would change a 0.1 year decrease in life expectancy to an increase of 0.1 year. With only two exceptions (injury and "other"), none of the variants of the other causes of death lead to a change in life expectancy of more than 0.2 years.

Table 3 also shows the effect on l_{65} of trend and target changes for each cause of death, assuming no changes in mortality for other causes. The same causes as above are also the most prominent in their effect on l_{65}. Unintentional injury deaths, however, achieve more prominence.

Because of competing risks, looking at changes in one cause of death at a time tends to diminish the apparent effect of health promotion and disease prevention efforts.[12] The chronic diseases, for example, are all related to a common set of risk factors (diet, smoking, alcohol, exercise) and would all tend to benefit from any increases in the accessibility of clinical preventive services for any one of them.[13] Therefore, we decided to look at the potential for reducing mortality for all chronic diseases. Similarly, since risk factors for injury deaths would tend to run together, we will also look at intentional and unintentional injuries taken together. Infant mortality is itself a combination of causes of death at ages under 1 year, and the final category is the combination of pneumonia and influenza with the residual "other," which includes AIDS and other infectious diseases.

Figure 3 and Table 3 show the impact of trend and targeted changes on e_0 and l_{65}. The major impact in either scale is still the chronic diseases (1.1 to 1.9 additional years of life expected at birth; 1.2 to 1.9 percentage point increase in the probability of living to age 65). Because they improve survival at younger ages, changes due to reduction in infant mortality and injuries are relatively more prominent in l_{65} than in e_0, but are still less important than changes in the chronic diseases.

Another way of looking at the projected changes is to look at the changes in the distribution of the causes of death. The distribution of deaths was determined by applying the projected age- and cause-specific mortality rates to the Census Bureau's median projected population for the year 2000.[14] The ranges indicate the highest and lowest proportions resulting from the three assumptions for nontargeted rates. Based on these calculations, chronic diseases fall from 72.7% to 70.5–71.2% of all deaths; the proportion of deaths due to injuries stays about the same: 6.1% to 5.8–6.1%; infant deaths fall from 1.3% to 1.0%; and other deaths increase from 20.0% to 21.9–22.4%. Clearly, achieving the targets would not mean a major shift in the distribution of causes of death, at least in these broad categories.

For specific causes, however, there are more marked changes. The largest drop is for heart disease: 36.9% to 31.8–34.1% of deaths. The proportion also goes down for stroke: 7.5% to 5.5–5.7%. For cancer, however, the proportion increases from 21.7% to 23.6–24.6%. COPD also increases, from 3.6% of deaths to 5.3–5.6%. The smaller shares for heart disease and stroke are nearly canceled out by the larger shares for cancer and COPD, leading to little overall change in the proportion of deaths from chronic diseases.

Reevaluation of Heart Disease and Injury Targets

Further analysis shows that the targeted reductions in heart disease and un-

intentional injuries are less than the trends would predict. Figure 4, for instance, shows trends in coronary heart disease since 1972. (As used in *Healthy People 2000*[1] and elsewhere by PHS, coronary heart disease refers to specific ICD codes within the broader category of Diseases of the heart.[15]) Depending on which years are used for trend analysis, the projected death rate for the year 2000 is either 90.8 or 92.6 per 100 000. The target is set conservatively at 100 per 100 000, although the trend data suggest that 90 per 100 000 might be a more reasonable level.

Figure 5 and Table 4 show that changing the target to 90 per 100 000 would have a major impact on the gain in e_0 (an additional increase of about 0.3–0.4 years) and in l_{65} (an additional increase of 0.3–0.4 percentage points). It would also affect the proportion of deaths due to heart disease and to chronic diseases. Assuming 1987 rates, 36.9% of all deaths are due to diseases of the heart. The percentage would fall to 29.5–32.4% with the new target. With the original heart disease target, this drop would only be to 31.8–34.6%. Similarly, the proportion of all deaths due to chronic diseases with 1987 rates is 72.7% and would fall to 69.6–70.4%. With the original heart disease target, this drop would only be to 70.5–71.2%.

Figure 5 and Table 4 also show the impact of a change in the target for unintentional injury mortality. A report has shown that accident mortality of all types has fallen by 21% between 1979 and 1989.[16] This rate of change is about double that called for in the PHS objectives. Changing the target from 29.3 to 22.0 per 100 000, consistent with the 10-year trend, would lead to a 0.2–0.3 year increase in life expectancy at birth and a 0.3–0.4 percentage point increase in the probability of surviving to age 65. The proportion of deaths due to all injuries would drop from 6.1% to 4.9–5.1% of all deaths.

Taken together, lowering both the heart disease and unintentional injury targets would increase overall life expectancy at birth by 0.6 years to 77.2–77.8 years. The probability of surviving to age 65 would increase by 0.6–0.8 percentage points.

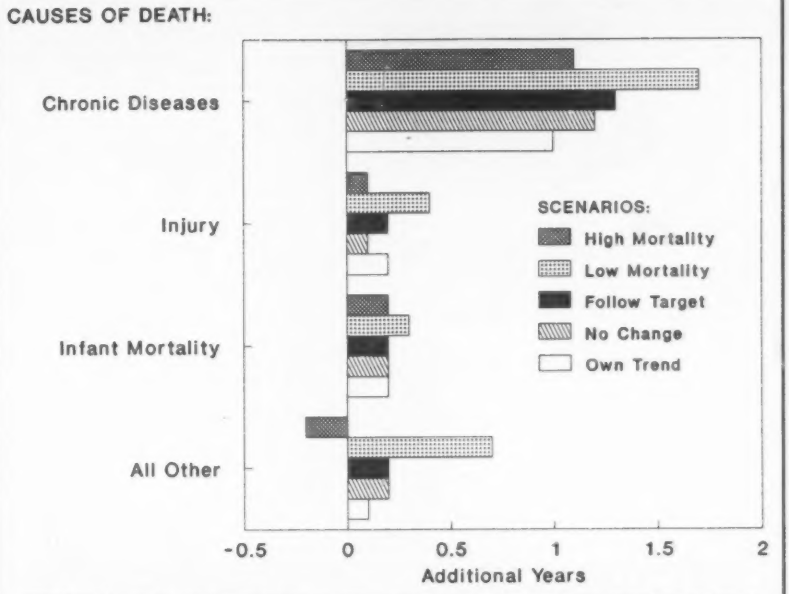

FIGURE 3—Projected increases in life expectancy at birth from trend and target changes in mortality from specified groups of causes: 1987–2000.

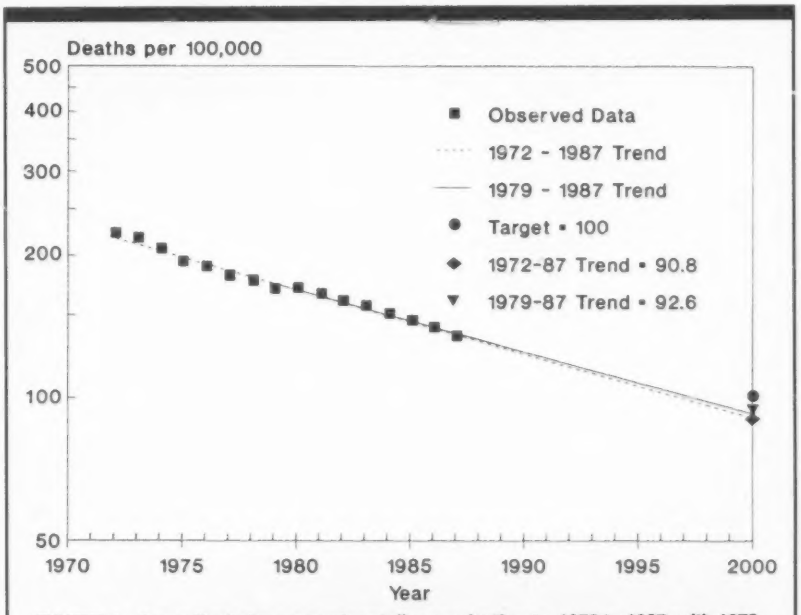

FIGURE 4—Age-adjusted coronary heart disease death rate, 1972 to 1987, with 1972–1987 and 1981–1987 trends projected to the year 2000, and year 2000 target rate (logarithmic scale, 1940 standard population). Data for 1972 to 1987 calculated by C. Sempos, National Center for Health Statistics, and provided by the Office of Disease Prevention and Health Promotion, US Public Health Service.

Discussion

Meeting the mortality targets set in *Healthy People 2000*[1] would have an important demographic impact. Taking the coronary heart disease and unintentional injury targets as stated in the objectives, the increase in life expectancy at birth would be 1.5 to 2.1 years, implying a life expectancy of 76.6 to 77.2 years. If the coronary heart disease and unintentional injury targets were changed to be somewhat more optimistic than the recent trend, life expectancy at birth would increase by 2.1 to 2.7 years to 77.2 to 77.8 years (see Figure 6). Trends in the cause-specific death rates used in this paper suggest an increase of 1.6–3.6 years to 76.7–78.7 years, with the lower end of the range being more likely. The results can also be

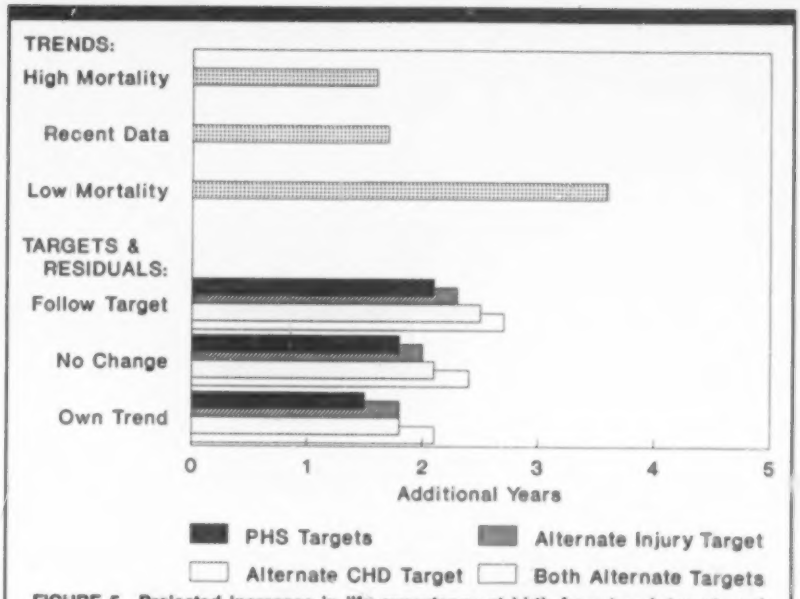

FIGURE 5—Projected increases in life expectancy at birth from trend, target, and alternative target changes in mortality from all causes: 1987–2000.

TABLE 4—Estimated Impact on e_0 and $_{45}l_{65}$ of Alternative Targets for Coronary Heart Disease and Unintentional Injuries and Their Associated Grouped Causes of Death: Year 2000

Causes of Death	Target Changes: Alternate Targets	Target and No Change in Residual	Target and Residual Trend
Added years of life expected at birth (e_0)			
All causes	2.7	2.4	2.1
Heart disease only	2.5	2.1	1.8

Injuries	0.4		
Unintentional injuries	0.3		
Increase in percentage surviving to age 65 ($_{45}l_{65}$)			
All causes	3.1	2.7	2.4
Heart disease ony	2.7	2.4	2.1
Unintentional injuries only	2.7	2.4	2.2
Chronic diseases	2.0	1.7	1.5
Heart disease	1.6	1.3	1.1
Injuries	0.7		
Unintentional injuries	0.6		

compared to ranges used in current Census Bureau[14] and Social Security Administration[17] projections of 75.3 to 78.9 years and 75.9 to 78.6 years, respectively. These are based on extrapolations as well, but using a different methodology. As Figure 6 shows, meeting the targets with the changes in the coronary heart disease and unintentional injury targets suggested above would put overall life expectancy above the middle of these ranges.

There are two reasons why demographic forecasters ought to note these results. First, they represent the substantive input of public health professionals asked to think about what might be achievable with known interventions. This kind of input is something that demographers would like to have but often cannot obtain. Second, the public health establishment is committed to making these changes come about. If progress reviews in mid-decade indicate that the nation is falling behind in measures needed to meet these targets, more resources might actually be brought to bear on interventions to reduce mortality, closing the feedback loop.

It is important to note, however, that the process used to set the targets might not have used the substantive knowledge of the experts as effectively as possible. Much of the energy used in setting the objectives has gone into discussions about which subjects should be included in the list of priority areas, into determining specific issues to be addressed within those areas, and into deciding how the objectives should be expressed in quantitative terms. In some cases, the specific numerical targets emerged after careful analyses and thought, but in others they were set at the last minute with little technical or substantive input. The process might have been improved if the content and the measures of the objectives had been determined first, and then a concerted effort made across the board to set target levels based on trend analyses and mathematical models that were feasible, realistic, and internally consistent.

Meeting the objective for reductions in activity limitation would lead to an additional 2.5 to 2.9 years of limitation-free life at birth and 1.4 to 1.8 years of limitation-free life after age 65. Chronic conditions of the circulatory system and injuries are major causes of disability as well as mortality.[18] Depending on whether increased survival consistent with the targets suggested in this article comes about through primary prevention or through better medical treatment of persons with heart disease and injury, further improvements in limitation-free years may be possible. Our analysis, however, focuses on mortality rather than other important health status variables such as morbidity and disability, and the available information does not permit explicit calculations.

The analysis does not specifically study the effect of projected changes in risk factors and preventive services. Nor does it address the question of different age patterns of change in mortality rates. The analysis needs to be expanded in order to appreciate the full range of benefits to be achieved and to better understand the contributions that various interventions can make to improvements in health status. As discussed above, this has not been possible for two reasons: lack of a consistent framework for nonmortality health status measures and lack of com-

plete information on the effect on health status of changes in risk factors and use of preventive services.

Progress in expanding the discussion beyond mortality alone depends on the development of consistent, systematic, and timely measures of health status, risk factors, and preventive services. Data from the annual NHIS are used for many of the objectives, and with changes in the objectives and the survey a more integrated system might be achievable.

Erickson and her colleagues have suggested that composite health status measures that incorporate morbidity, disability, and quality of life could be obtained from the NHIS, and that these could be the basis for the calculation of a measure of quality-adjusted life years (QALY) that is analogous to life expectancy except that each year of life is discounted by the average "quality of life" people experience at that age.[19] To the extent that the year 2000 objectives for the prevalence of specific conditions relate to the measures that go into the QALY calculation, the impact of meeting those objectives could be summed up in the same way we have done here for objectives on mortality levels.

Because the PHS objectives are generally stated in terms of overall death rates without specific mention of age or sex patterns, we assumed for this analysis that the same percentage change applied to all age-specific death rates and did not differentiate by sex. The current patterns of risk reduction and use of preventive services probably do not result in the same percentage reductions in death rates at all ages, as we were forced to assume. Clearly, further analysis needs to be used using more complex models of mortality decline than the ones we have used. Manton and his colleagues[20] and Olshansky,[21] for instance, have investigated the impact of delaying the progression of chronic diseases, not reducing their incidence.

Making the link between changes in risk factors and preventive services to health status measures will require two things. First, we need more extensive epidemiological studies on the prevalence of risk factors and the effect of changes in risk factors and preventive services on a full range of health status measures. Furthermore, preventive interventions must be carefully evaluated so that their population impact can be better understood. Second, more extensive demographic and epidemiological modeling efforts are needed to bring this information together so that the impact of changes in risk factors and access to clinical preventive services can be better predicted. There is some work in this area that could be drawn on,[22–27] but generally for one disease or risk factor at a time, and it is difficult to integrate this information.

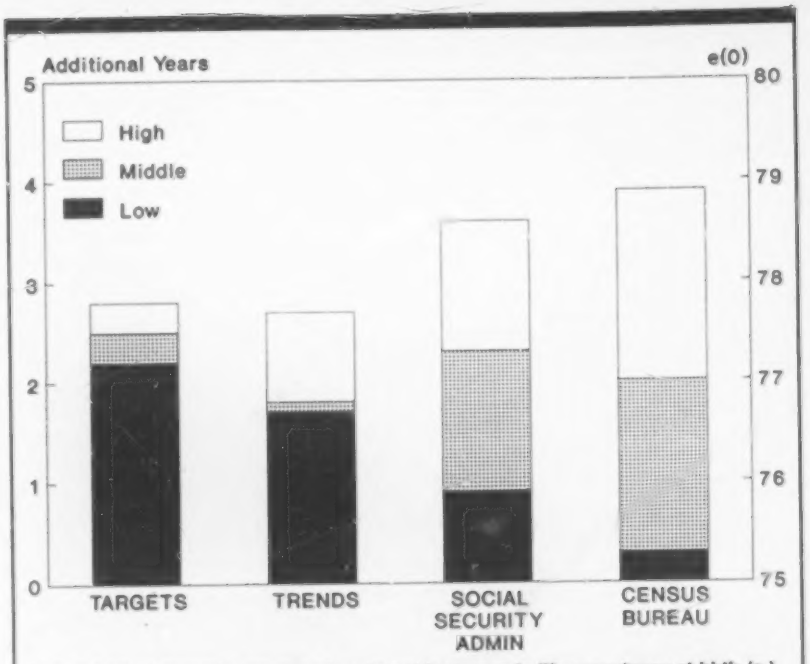

FIGURE 6—Alternative ranges of projected increases in life expectancy at birth (e_0) from 1987 to 2000 and of projected values of e_0 in the year 2000: PHS targets, trends, Social Security Administration, and Bureau of the Census. Census Bureau values are arithmetic averages of separate projections for males and females. From Spencer[14] and Wade[17].

Models of this sort can also shed light on the age-specific impact of preventive interventions that is lacking in this analysis. Manton, for instance, argues that risk factors and mortality reductions have a very different relationship at older ages than they do at younger ages.[28] Two kinds of issues need to be explored. First, detailed studies of the actual patterns of mortality reductions would lead to a fuller understanding of the demographic impact of meeting the year 2000 objectives. Second, we need to explore the impact of interventions targeted at different age groups and thus get a better idea about the most effective way to manage health promotion and disease prevention interventions. □

Injury Prevention Awareness in an Urban Native American Population

James S. J. Hsu, BS, and Scott D. Williams, MD, MPH

ABSTRACT

The injury-related mortality rate for Native American children between the ages of 1 and 4 years is nearly three times that of the same age group in the general population. To assess injury prevention awareness in urban Native American families, we administered 39 age-appropriate questions from the Framingham Safety Survey to 50 Native American families and 100 other families and developed an answer scoring system to analyze and compare survey responses. Survey responses revealed that Native American families are less likely to keep small objects, household products, and medicines out of the reach of their children and to possess and understand the use of ipecac. Although urban Native-American families appear to be less aware of ingestion prevention practices than other urban families, these and other deficiencies in injury prevention awareness are more likely the result of factors related to their low-income status than to culturally based practices. (*Am J Public Health.* 1991;81:1466–1468)

Introduction

Although nearly half of all Native Americans now live in urban areas, little data are available describing the health status for this segment of the population. Health statistics reported by the Indian Health Service often describe only reservation-dwelling Native Americans. Among Native American children between 1 and 4 years of age, injury-related deaths occur at nearly three times the rate of the same age group among the general population in the United States.[1–4] As with most accident-related injuries and deaths, a large portion of those involving Native American children may be preventable. Urban conditions such as poor housing, limited access to health care, inadequate day care, and increased exposure to physical hazards may further increase the risk of injury for urban Native American children.

Injury prevention awareness is commonly evaluated in the clinical setting by parent survey techniques such as the Framingham Safety Survey (FSS), recommended and distributed by the American Academy of Pediatrics (AAP) through The Injury Prevention Program (TIPP).[5] These survey methods have never been studied for their usefulness in identifying injury prevention awareness in the Native American population. In this study we attempted to determine whether parents in an urban Native American population are as aware of, and as likely to practice, injury prevention techniques as parents in other urban families.

Methods

In this cross-sectional study, we enrolled 150 families with children between the ages of 1 and 4 during the 4-month period from June 1988 to September 1988. Fifty families were interviewed at each of three clinics in the same urban area: (1) the Indian Health Care Clinic, a primary health care clinic for Native American families; (2) the Salt Lake City–County Health Department Clinic, a primary health care clinic for low-income families; and (3) a university-based private pediatric practice.

To assess injury prevention awareness in these families, a trained interviewer verbally administered 39 age-appropriate questions, taken from the FSS, to a parent from each enrolled family while the families were waiting at the clinic for a well-child or sick-visit appointment. A scoring method was devised to quantify the risk of injury. A score of 1 was given for low-risk, 2 for moderate-risk, and 3 for high-risk behavior. A total score was computed for each family, the lower total scores being associated with a lower risk of injury. The results were analyzed for statistical significance using the Student's *t* test, the Kruskal-Wallis test, and the Mann-Whitney test. Statistical significance was determined at the $P < .05$ level.

Results

Characteristics of the families in the sample are presented in Table 1. There was a significant difference in income between families at the three clinics ($P = .001$), with families at the urban Indian clinic having a lower mean annual income than families at either of the other

two clinics. When families were stratified into a low-income (<$15 000/year) group and a higher income (>$15 000/year) group, the Native American families within the low-income group had a significantly lower mean annual income than other families in the low-income group ($P = .01$). Further income stratification was not performed because of limitations of the sample size.

Table 2 presents the item scores on questions where statistically significant differences existed between groups. Of the 39 injury prevention awareness questions, Native American families received higher risk scores on questions 1 through 4, even after controlling for income. Low-income families, in general, received higher risk scores on questions 1, 2, and 5 through 8. Higher income families received higher risk scores on questions 9 through 11.

Total scores are also presented in Table 2. A Native American revised score was computed, eliminating questions 1 through 4, to look for a cumulative injury prevention awareness deficiency among Native American families beyond the questions where statistically higher scores were found. To create a similar measure among all low-income families, a low-income revised score was computed, eliminating questions 1, 2, and 5 through 11.

TABLE 1—Characteristics of the Injury Prevention Awareness Study Population

[a]Native American revised total score = total score − questions 1–4.
[b]Low-income revised total score = total score − questions 1, 2, and 5–11.

icantly higher scores than other low-income families. These four items are all related to ingestion events and reveal a situation where families are lacking understanding of both prevention and intervention strategies in this specific area. Because of the significant difference in income between Native American and other families, a difference that persisted even within the low-income stratum, we cannot be sure that even these four indicators of relative deficiencies in injury prevention awareness would not have been eliminated with a larger sample size including more "very-low-income" controls.

Poverty alone is known to be associated with an increase in injury-related deaths.[6–8] When compared with the higher income group, low-income Native American families displayed other deficiencies in injury prevention awareness that were common to all low-income families when compared with the higher income group. Although income bias may exist in some of the questions, the questions still reveal situations where lack of money or lack of control over housing conditions leaves a family unable to comply with injury prevention strategies such as regularly checking the heating system, using smoke detectors, and possessing a fire extinguisher. The lack of significant differences in low-income revised scores leads us to conclude that, beyond the differences revealed by individual items, no cumulative difference exists in injury prevention awareness between the low-income and higher income groups.

Care must be taken when interpreting the responses to certain items. For example, the question revealing less awareness of car seat type among low-income families may reveal a higher use of borrowed or handed-down car seats in these families, or alternatively may actually suggest a lack of confirmation regarding the family's possession and use of a car seat. Furthermore, in many instances, the "correct" response is well understood but may not actually be practiced. This suggests the possibility of obtaining falsely reassuring responses. Therefore, while responses indicating a lack of injury prevention awareness may provide guidance to the clinician in focusing health education strategies with a particular family, "correct" responses may not be enough to allow the clinician to make presumptions regarding the family's compliance.

We have demonstrated that, in families using an urban Native American clinic, there is less awareness of ingestion-related injury prevention and intervention strategies than in families using other urban clinics, although our study population was not large enough to completely eliminate income as an explanation for this difference. As members of the larger low-income urban population, urban Native American families revealed other deficiencies in injury prevention awareness or practice when compared with higher income families. Factors contributing to the increased risk of injury-related morbidity and mortality among Native American children seem to be more strongly associated with economic conditions than culturally based differences in parenting in the urban families we studied. □

AIDS Surveillance among American Indians and Alaska Natives

Russ Metler, RN, MSPH, George A. Conway, MD, MPH, and Jeanette Stehr-Green, MD

ABSTRACT

To assess the human immunodeficiency virus epidemic among American Indians and Alaska Natives (AI/AN), we examined acquired immunodeficiency syndrome (AIDS) case and seroprevalence data through December 1990. While AI/AN had a low 1990 reported AIDS case rate (4.0/100 000), the increase in diagnosed cases adjusted for reporting delays from 1989 to 1990 was higher (23.1%) among AI/AN than any other racial/ethnic group. Seroprevalence data for military applicants have documented higher rates for AI/AN than for either Whites or Asian/Pacific Islanders. (*Am J Public Health.* 1991;81:1469–1471)

Introduction

Although the population of American Indians and Alaska Natives (AI/AN) is small (less than 2 million), it includes highly diverse cultures and geography. Compared with the total US population, AI/AN are younger, less educated, less likely to be employed, and poorer.[1] These factors, combined with high rates of sexually transmitted diseases[2–5] and drug use among AI/AN,[6,7] may favor the spread of the human immunodeficiency virus (HIV).[8] We compared selected demographic and risk characteristics among AI/AN with the acquired immunodeficiency syndrome (AIDS) and persons with AIDS of other racial/ethnic groups reported to the Centers for Disease Control (CDC) through 1990.

Methods

State and local health departments in the United States report AIDS cases without personal identifiers to CDC. Among the variables collected are risk factors for HIV infection, setting where first AIDS diagnosis was made, and race/ethnicity (White, Black, Hispanic, Asian/Pacific Islander [A/PI], and AI/AN). Race/ethnicity is generally determined from available medical records.

AIDS cases reported to CDC as of December 31, 1990, were compared by race/ethnicity. Population data for rate calculations were based on 1990 census estimates.[9]

For AI/AN cases, the hospital of AIDS diagnosis was compared for type of organization in the *American Hospital Association Guide to the Health Care Field.*[10] Nonhospital facilities were coded consistent with the American Hospital Association's classification scheme.

All civilian applicants for US military service are tested for HIV infection.[11,12] From data provided by the Office of the Assistant Secretary of Defense (Health Affairs), HIV results for military recruit applicants examined from October 1985 through December 1990 were analyzed by race/ethnicity. Of the 2 946 895 applicants screened, 20 036 (0.7%) were AI/AN.

Results

AI/AN had 237 AIDS cases reported through 1990, the lowest cumulative total of any race/ethnicity. The rate of reported AIDS cases per 100 000 population for 1990 was low for AI/AN (4.0) relative to Blacks (42.5), Hispanics (31.9), and Whites (11.8). The rate for AI/AN was similar to that for A/PI (3.8). Comparisons based on cases diagnosed in 1989 and 1990, with adjustments made for reporting delay, showed AI/AN with the greatest relative increase (23.1%), compared with Hispanics (13.3%), Blacks (12.0%), Whites (2.5%) and A/PI (−8.8%).[13]

The exposure category distribution of AI/AN AIDS cases differed from other groups, with a smaller proportion of cases attributed to homosexual/bisexual contact (53%) than Whites (76%) but a higher proportion than for Blacks (35%) or Hispanics (39%) (Table 1). The proportion of cases attributed to intravenous drug use among women and heterosexual men in AI/AN (16%) was greater than for Whites (8%), but less than for Blacks (38%) and Hispanics (39%). AI/AN had the lowest male-to-female ratio of AIDS cases due to intravenous drug use. Of 37 AI/AN women with AIDS, 17 were intravenous drug users and 5 were heterosexual contacts of intravenous drug users. Overall, 79 (33%) of the AI/AN AIDS cases had risk factors associated with intravenous drug use.

Nearly half the AI/AN with AIDS were first diagnosed at either a federal or nonfederal government facility (Table 2). However, only 9% of all cases were initially diagnosed at an Indian Health Service (IHS) facility. In four states (Alaska, Arizona, New Mexico, and Oklahoma) with a high percentage of AI/AN served by IHS (data provided by the Division of

Indian Health Service	22	9
Veterans Administration and other federal	11	5
Nongovernment	109	46
Church	26	11
Other	83	35
Not categorized[a]	12	5
Total	237	100

[a]Not categorized because of insufficient information provided on the case report.

Program Statistics, IHS, January 1988), 23 of 53 (43%) AI/AN AIDS cases were IHS diagnosed. In New York and California, where most AI/AN individuals are not served by IHS, none of the 75 AI/AN AIDS cases were initially diagnosed by IHS.

Among civilian applicants for military service, 17 AI/AN were HIV-antibody positive. Seroprevalence rates per 1000 were higher for AI/AN (0.8) than for Whites (0.5) and A/PI (0.4) but lower than those for Blacks (3.3) and Hispanics (1.8).

Discussion

The HIV epidemic among AI/AN may be more extensive than previously recognized. AI/AN had the largest percentage increase in diagnosed cases from 1989 to 1990 among all racial/ethnic groups. Data from applicants for military service and reports on racial misclassification, AI/AN drug use, and sexually transmitted disease rates support this possibility.

Among civilian applicants to military service, AI/AN HIV seroprevalence rates are higher than those for Whites. This higher rate relative to AIDS case rates might be the result of (1) the possibility that military recruit applicant screening data do not accurately represent the HIV infection rate for each racial/ethnic group, (2) HIV having only recently entered the AI/AN population, and (3) race ascertainment possibly differing for AIDS cases and applicants.

The incidence of AIDS among AI/AN may be higher than recorded, especially in nonreservation areas, because of racial misclassification. Several studies have documented racial misclassification in health reports,[14–16] and misclassification of AI/AN AIDS cases has been found in two cities (M. G. Hurlich, written communication, June 1990).[17]

Studies comparing drug use among AI/AN youth and non-AI/AN youth have revealed higher rates of drug use among AI/AN than non-AI/AN.[6,7] Overall, one third of all AI/AN cases were in some way associated with intravenous drug use.

High sexually transmitted disease rates could be a factor in the HIV epidemic among AI/AN. The presence of sexually transmitted diseases may facilitate HIV transmission[18–21] and reflect high-risk sexual activity. From 1984 to 1988, in the 13 states where 59% of the nation's AI/AN population reside, the mean rates of gonorrhea and primary and secondary syphilis in AI/AN were more than twice those for non-AI/AN.[2]

IHS facilities provide services for approximately 61% of the entire AI/AN population;[2] however, only 22 (9%) AI/AN AIDS cases were initially diagnosed at these facilities. This might reflect lower availability of IHS services in geographic areas with higher numbers of AI/AN AIDS cases.

Although the rate of reported AIDS cases in AI/AN has been relatively low, AIDS surveillance and HIV seroprevalence data clearly show that HIV has entered the AI/AN population, with diagnosed AI/AN AIDS cases increasing more rapidly than in any other racial/ethnic group. In addition, disturbingly high sexually transmitted disease and drug use rates have been reported among AI/AN. Culturally sensitive prevention programs for AIDS, sexually transmitted diseases, and intravenous drug use must be refined and expanded to decrease further spread of HIV among American Indians and Alaska Natives. □

Hearing Loss and Hearing Aid Use in Hispanic Adults: Results from the Hispanic Health and Nutrition Examination Survey

David J. Lee, PhD, Deborah L. Carlson, PhD, Heidi M. Lee, MA, Laura A. Ray, MA, and Kyriakos S. Markides, PhD

ABSTRACT

Data from the Hispanic Health and Nutrition Examination Survey were employed to investigate the prevalence of hearing loss and hearing aid use in Mexican-American, Cuban-American, and Puerto Rican adults. Hearing loss was 6 to 14 times more prevalent in older (ages 54 to 74) vs younger (ages 20 through 34) subjects. Cuban Americans and Mexican Americans tended to have a similar prevalence of hearing loss, whereas Puerto Ricans had markedly lower rates. Mexican-American men had higher rates of hearing loss than Mexican-American women. The prevalence of hearing aid use among hearing-impaired individuals ranged from 2% to 11%. Implications for future research are discussed. (*Am J Public Health.* 1991;81:1471–1474)

Introduction

An estimated 28 million people in the United States are afflicted with hearing loss.[1] Hearing impairment is the fifth most prevalent chronic health condition and the second most prevalent impairment[2] in the nation. The prevalence of hearing loss is significantly greater in the elderly and also in men.[1,3] African Americans have lower rates of hearing loss than non-Hispanic Whites,[4–6] possibly because greater cochlear pigmentation may reduce the risk of noise-induced hearing loss.[7]

There have been several national population-based audiometric surveys of non-Hispanic Whites and African Americans,[4–6] but only recently has a similar survey been undertaken on the US Hispanic population. This report provides prevalence estimates of hearing loss and hearing aid use in Hispanics using data from the Hispanic Health and Nutrition Examination Survey (HHANES).

Materials and Methods

The HHANES was conducted from 1982 to 1984 by the National Center for Health Statistics. The HHANES employed a complex multistage sampling design aimed at obtaining a representative sample of Mexican Americans in the Southwest (Texas, New Mexico, Colorado, Arizona, and California), Cuban Americans in the Miami area (Dade County), and Puerto Ricans in the New York City area.[8,9] Response rates for the physical examination where audiometric data were collected were 76.1%, 60.8%, and 75%, respectively, for Mexican Americans, Cuban Americans, and Puerto Ricans.[8]

Our analysis is limited to adults aged 20 to 74. Pure tone audiometric data were collected on one half of the subjects participating in the physical examination (Mexican-American n = 1682, Cuban-American n = 441, and Puerto Rican n = 628). All subjects were alternately assigned to audiometric or other medical testing when they scheduled their medical examination. Participants were asked during the physical examination whether they had ever used a hearing aid.

Audiometric testing was conducted in a sound-treated booth using calibrated audiometric equipment.[10,11] Air conduction thresholds were obtained at 500, 1000, 2000, and 4000 Hz, with testing repeated at 1000 Hz. Masked hearing thresholds were obtained using narrow-band noise in the nontest ear when there was an interear difference in air conduction thresholds[11] greater than 40 dB.

Pure tone average thresholds (PTAs) were calculated by averaging thresholds obtained at frequencies of 500 Hz, 1000 Hz, and 2000 Hz.[12] The better of the two threshold responses at 1000 Hz was used in PTA calculation. Masked threshold values were used when indicated. Hearing loss was defined as a PTA of greater than 25 dB in either ear.[12] PTAs were not calculated on subjects with incomplete bilateral audiometric data (n = 28) or when there was probable equipment failure (n = 5).

Analyses were calculated separately for men and women within the three ethnic groups using the general linear model and logistic regression programs from SAS.[13] Age-adjusted percentages were also calculated to make gender-specific comparisons within each of the three ethnic groups.[14,15] Because of the multistage sampling design, analyses were performed with adjustments for sample weights and design effects.[8,9]

Results

Table 1 presents the prevalence rates of hearing loss by age group, ethnicity, and gender. There was a significant increase in the prevalence of hearing loss with increasing age within each ethnic by gender comparison. Prevalence rates ranged from 2% to 7% and 24% to 48% in the youngest and oldest age groups, respectively. Results by ethnicity indicate that, in general, the Puerto Ricans had a lower prevalence of hearing loss.

Table 2 presents the prevalence of mild (26 through 40 dB) and moderate or greater (> 40 dB) hearing loss by age group, gender, and ethnicity. Generally, mild hearing loss was more prevalent than moderate or greater hearing loss. Furthermore, the prevalence of moderate or greater hearing loss exceeded 10% in only the oldest age group. The prevalence of mild hearing loss significantly increased across age groups. The prevalence of moderate or greater hearing loss significantly increased by age group among Mexican Americans and Cuban Americans, but not Puerto Ricans. The prevalence of moderate or greater loss among Puerto Ricans in the 55 to 74 age group was markedly lower than in Mexican Americans and Cuban Americans.

Table 3 presents the age-adjusted prevalence of hearing loss by gender. Hearing loss prevalence was generally higher in men than in women, although these differences were statistically significant only for Mexican Americans when

examining overall (> 25 dB) and mild (26 through 40 dB) hearing loss.

Table 4 presents the age-adjusted prevalence of hearing aid use by gender and ethnicity. The prevalence of hearing aid use was less than 10% in each ethnic by gender comparison. Inconsistent nonsignificant gender differences in hearing aid use were noted. The prevalence of hearing aid use among Mexican-American men and women with moderate and greater hearing loss (> 40 dB) was 5.4% (± .05) and 11.1% (± .05), respectively.

TABLE 3—Prevalence of Mild, Moderate, and Overall Hearing Loss by Gender

	Men		Women		
	%	SE	%	SE	χ^2
Mild (26–40 db)					
Mexican Americans	10.5	.01	6.9	.01	7.5*
Cuban Americans	15.3	.02	14.1	.02	0.2
Puerto Ricans	6.6	.02	8.4	.01	0.7
Moderate (> 40 db)					
Mexican Americans	5.3	.01	3.9	.01	1.9
Cuban Americans	7.5	.02	6.4	.02	0.3
Puerto Ricans	3.6	.01	1.8	.01	2.3
Overall (> 25 db)					
Mexican Americans	15.8	.01	10.9	.01	10.3*
Cuban Americans	22.7	.03	20.4	.02	0.5
Puerto Ricans	10.3	.02	10.2	.01	0.0

Note. Prevalence estimates are age-adjusted. Logistic regression techniques were used to test gender group differences.
*$P < .01$.

TABLE 4—Prevalence of Hearing Aid Use by Gender among Hispanics

	Men		Women		
	%	SE	%	SE	χ^2
Overall (> 25 db)[a]					
Mexican Americans	3.7	.02	3.9	.02	0.2
Cuban Americans	1.9	.03	6.7	.03	0.6
Puerto Ricans	9.9	.05	4.9	.05	1.6
Moderate (> 40 db)[b]					
Mexican Americans	5.4	.05	11.1	.05	0.8

Note. Prevalence estimates are age-adjusted.
[a]Denominator includes all participants with > 25 db hearing loss.
[b]Denominator includes all partipants with > 40 db hearing loss. Because of sample size limitations, only results for Mexican Americans are reported. These estimates may be unstable as a result of analytic sample sizes less than 45 (men = 37, women = 38).

Discussion

The present study confirmed that hearing loss—considered to be the second most prevalent impairment in the United States[2]— is also highly prevalent in the Hispanic population. The expected increase in prevalence with advancing age was also observed. A higher prevalence of hearing loss for men, reported elsewhere,[3,7] was confirmed only in Mexican-American men.

The findings by ethnicity suggest that Puerto Ricans have an overall lower prevalence of hearing loss relative to the other two ethnic groups. Possible hypotheses to account for these findings include the following: (1) there are genetic or anthropomorphic characteristics among Puerto Ricans that perform a protective function;[7] and (2) Puerto Ricans in the present study may have experienced less lifetime exposure to damaging levels of noise.[1]

A low prevalence of hearing aid use has been documented in previous research with estimates ranging from 6% to 14%.[3,16] In this report, prevalence rates remained below 12% even when examining Mexican Americans with 40 dB or greater hearing loss. Virtually all individuals with such a loss would benefit from hearing amplification.[17] Factors that may contribute to low hearing aid use include cost and low consumer awareness of the benefits of amplification.[16] Future research should focus on identification of hearing-impaired individuals and the development of culture- and language-specific interventions designed to increase hearing aid use in Hispanics. □

Interpersonal Violence-Related Injuries in an African-American Community in Philadelphia

Amy R. Wishner, RN, MSN, Donald F. Schwarz, MD, MPH, Jeane Ann Grisso, MD, MSc, John H. Holmes, MS, and Rudolph L. Sutton, MPH

ABSTRACT

Violence has been recognized as a significant health problem. This study describes fatal and nonfatal interpersonal violence-related injury events over 1 year in an indigent African-American community in Philadelphia. Information on injuries was collected from emergency rooms, the Office of the Medical Examiner, and death certificate files. For persons aged 15 through 49 years, violence-related injury rates surpassed any other injury type. The overall violence-related injury rate was 28.7 per thousand population. Interpersonal violence-related injuries were important for the 0- to 4-year age group (9.19 injuries per 1000 population), and continued as a major cause of morbidity through age 59 (12.08 injuries per 1000 population). For more than half of the events, information from the emergency room chart was sufficient only to categorize the incident as a "fight" or that it was intentional; no further classification was possible. (*Am J Public Health.* 1991; 81:1474–1476)

Introduction

Little information is available about the larger problem of violence that underlies homicide in inner-city communities. The current study was carried out by the Philadelphia Injury Prevention Program (PIPP), a cooperative effort of the Philadelphia Department of Public Health, Children's Hospital of Philadelphia, the University of Pennsylvania School of Medicine, the Centers for Disease Control, and a local citizens' advisory board. The study involved fatal and nonfatal interpersonal violence-related injuries (IVRI) in a geographically defined community seen over a 1-year period in emergency rooms, the Office of the Medical Examiner, and death certificate files.

Methods

Study Communities and Case Definition

The neighborhoods in this study comprised 17 census tracts with 68 103 residents in Philadelphia. The population was 97.2% African American, with a median family income of $11 810.

Information on all injuries occurring to residents of the study area was collected by an active emergency room surveillance system, outlined elsewhere.[1] An injury was defined as a case if the event occurred to a resident of the study area and led to emergency room evaluation at a hospital in the injury surveillance network or resulted in death between March 1, 1987, and February 29, 1988.

Trained medical abstractors ascertained from a patient's emergency room chart whether or not an injury occurred and was inflicted by another person in a manner that could be characterized clearly as assaultive or intentional. These injuries were included in the IVRI category. On the basis of the medical record, IVRI were classified as child abuse (cases of abuse up to age 19), rape, stabbing, firearm, or other assault.

Data Collection and Analysis

Data collection, quality control, and analysis have been described previously.[1] Briefly, each injury event was coded according to the International Classification of Diseases, 9th revision, Clinical Modification (ICD-9-CM) External Cause of Injury Codes (E-codes) by an experienced medical coder (see the Appendix for the E-code categories making up each classification). For events with more than one E-code, two of the authors independently assigned a principal code to that event that initiated the sequence leading to physical injury.

Time of entry to an emergency room was classified as morning (6:00 AM to

Amy R. Wishner and Rudolph L. Sutton are with the Philadelphia Department of Public Health. Donald F. Schwarz and John H. Holmes are with The Children's Hospital of Philadelphia, and Jeane Ann Grisso is with the University of Pennsylvania School of Medicine.

11:59 AM), afternoon (12 noon to 5:59 PM), evening (6:00 PM to 11:59 PM), or night (12 midnight to 5:59 AM).

Results

A total of 1958 IVRI were identified. The IVRI rate surpassed the rate for any other injury type for persons aged 15 through 49. For all ages, IVRI had the second highest injury rate per thousand residents (28.7) of any type of injury, less than falls (31.7) and greater than motor vehicle incidents (22.0).

There were 1690 persons who sustained IVRI; 100 individuals had more than one IVRI. Fourteen individuals (7 males and 7 females) had three or more IVRI during the single year of surveillance.[2] (In the *MMWR* article,[2] one injury related to legal intervention and one suicide attempt were included in the definition of repeated violence-related injuries.)

Violence resulted in more deaths than did any other injury type, 44% of all injury deaths, for a death rate of 60.2 per 100 000 population. Among the 64 males and 29 females who died as a result of injury, 32 (50%) and 9 (31%), respectively, died from violence.

The total number of IVRI, by type of violence, can be seen in Table 1.

Injured Persons

IVRI occurred predominantly among those aged 15 through 39 years, who composed 38% of the population and experienced 72.2% of all IVRI. The rate of IVRI among males (40.5 per 1000 males) was approximately twice the rate for females (19.4 per 1000 females). Males constituted 44.3% of this population and experienced 62.4% of the IVRI (Figure 1).

Injury Events

Time of admission to the emergency room was noted in 98.1% (1920) of IVRI. Cases were more likely to enter an emergency room during evening hours (658, or 34.3%) than at night (475, or 24.7%), afternoon (476, or 24.7%), or morning (311, or 16.2%). Approximately one third (620, or 32.1%) of the 1931 IVRI entered an emergency room on a Saturday or Sunday.

The greatest number of IVRI cases entered emergency rooms in the summer months of June (214, or 10.9%), July (187, or 9.6%), and August (180, or 9.2%). The 74 firearm injuries had a different pattern, with the greatest number entering emergency rooms in November and December (11, or 14.9%, and 9, or 12.2%, of firearm injuries, respectively).

Information on alcohol or drug involvement, and where the injury event took place, was rarely recorded. Alcohol involvement was recorded in 7.1% (139) of cases, drug involvement in 1.1% (21), and location in 20.2% (396).

Hospital Admissions. There were a total of 107 hospital admissions, a rate of 5.5 per 100 IVRI. Among males, who had higher hospital admission rates for each category of violence-related injury, firearms ranked first with 28 admissions, 36 for stabbing, and 30 for other assaults. Females had 1 hospital admission for firearms, 2 for stabbing, and 10 for other assaults.

Deaths. Firearm-related injuries had the highest case-fatality rate (CFR) per 100 cases, a sex-specific CFR of 26.5 for males (18 deaths) and 16.7 for females (1 death). Both males and females had a CFR of 3.4 for stabbings, with 8 and 2 deaths, respectively. Other assaults had markedly lower CFRs, 0.8 (6 deaths) for males and 0.9 (4 deaths) for females. Among females, there was 1 death due to a rape and 1 death due to child abuse.

Abuse. There were 63 cases of abuse to children from birth through age 19, a rate of 3.28 per 1000 children.

Rape. Seven rapes were reported, all among females. Six occurred among females aged 15 through 34.

TABLE 1—Total Number of Interpersonal Violence-Related Injuries by Type of Violence

Type of Violence	No. of Events	Rate per 1000 Population
Abuse	63	3.28[a]
Rape	7	0.10
Stabbing	296	4.35
Firearms	74	1.09
Other assaults	1518	22.29
Total	1958	28.71

[a]Rate per 1000 population 0–18 years of age.

Stabbing. Of the 296 stabbings, 80.1% (237) involved male victims. Rates among males peaked in those aged 20 through 24 years, whereas among females stabbing rates peaked among an older age group, those aged 25 through 29 years (Table 2).

Firearms. As with stabbings, firearm injuries increased dramatically beginning in those aged 15 through 19, and among males remained high through ages 40 through 44 (Table 3).

Other Assaults. Assaults not otherwise categorized constituted 77.5% of IVRI, with 1518 events (Table 4). Little information was available about the majority of other assaults; 484 could be classified only as fights, and 578 were not specified as to cause of IVRI.

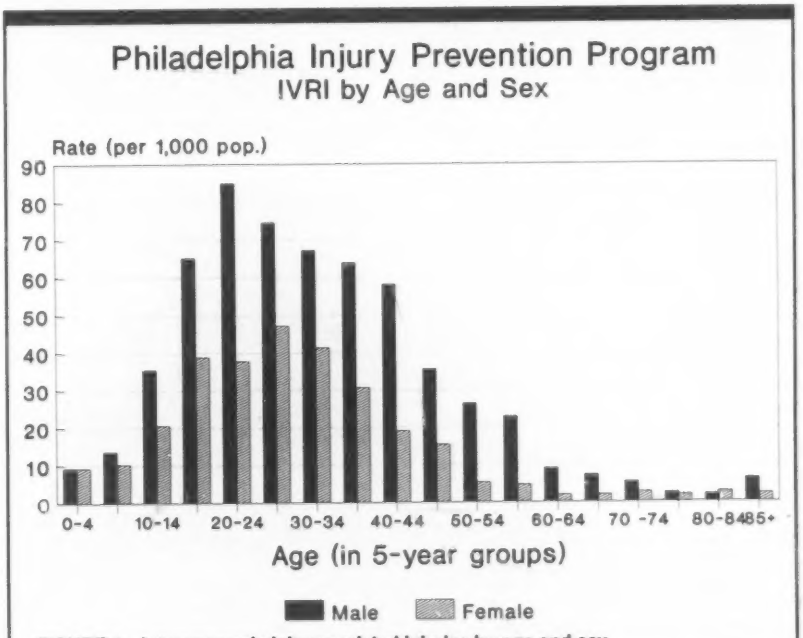

FIGURE 1—Interpersonal violence-related injuries by age and sex.

TABLE 2—Stabbing Rates by Age and Sex (per 1000 population)

[a]Excludes two other assaults where either age or sex could not be ascertained.

Discussion

These data provide compelling evidence of (1) the magnitude of the problem of violence-related injuries, (2) the need to look beyond homicide and firearm-related data and include stabbings and assaults to appreciate the full spectrum of violence-related injuries, (3) the need to address violence occurring to preschool and elementary school–aged children, and (4) the need for more comprehensive information to be recorded in emergency room charts.

Focusing on fatalities neglects the impact of stabbings and other assaults, more frequent causes of injury to young people.

In PIPP's data, child abuse and other assaults that were seen in the 0 through 4 age group are of particular concern. Observing or being the victim of violence early in life may predispose one to committing or being a victim of violence in adult years.[3–6]

Limitations of the Data

Emergency room records may not always indicate intentional incidents.[7] Thus, the rates reported in this study are conservative estimates. Rape was especially underreported in this study, as the two Philadelphia hospitals with rape treatment programs were not in the surveillance network.

PIPP's study pinpoints needed but inconsistently available data, including alcohol/drug status, victim–perpetrator relationship, time of the injury event, where the injury event took place, characterization of assaults, living arrangements and social support, history of the injury event, previous violence involving the patient either as victim or perpetrator, roles of witnesses and the police, weapon-carrying behavior, and presence of weapons in the household.

Conclusion

The data presented above on fatal and nonfatal IVRI events in a geographically defined African-American community provide dramatic evidence of the staggering extent of violence. We face the urgent task of applying these data in making use of existing violence prevention programs, developing new efforts, evaluating their effectiveness, and improving the data available to help design such projects if they are to have an impact on the important public health problem of violence. □

Physical Activity and Hypertension in Black Adults: The Pitt County Study

Barbara E. Ainsworth, PhD, MPH, Nora L. Keenan, MPH, David S. Strogatz, PhD, Joanne M. Garrett, PhD, and Sherman A. James, PhD

ABSTRACT

The relation of physical activity to hypertension was examined in 1751 Black adults in Pitt County, NC. More women (65%) than men (44%) were classified as sedentary. Sedentary behavior was not associated with the prevalence of hypertension in men, but was associated with a 31% increase in prevalence for women (sedentary-26.2%; active-20.0%; $P < .01$). The association in women was independent of other risk factors for hypertension. (*Am J Public Health.* 1991;81:1477–1479)

Introduction

Observational and experimental studies suggest that regular physical activity is inversely related to blood pressure.[1–4] However, little is known about physical activity and its relation to blood pressure in Black adults, despite the recognized excess risk of hypertension in Blacks.[5–10] Some surveys of physical activity have detected little difference by race,[11,12] but others have found Blacks to be less active.[10,13–18] In a study of risk factors for heart disease in young adults,[19] duration on a treadmill exercise test was significantly shorter for Blacks than for Whites. None of the reports on physical activity or fitness in biracial samples have race-specific analyses of the association with elevated blood pressure.

The purpose of this article is to describe the level of physical activity and the relation between physical activity and the prevalence of hypertension in a community-based sample of Black adults residing in Pitt County, NC.

Methods

The data for these analyses were collected in the 1988 survey of the Pitt County Study. The purpose of this survey was to provide baseline information for the prospective study of psychosocial and dietary risk factors for elevated blood pressure in Black adults 25 to 50 years of age. Selection of the probability sample and additional information about the study have been published elsewhere.[20] Of 2225 race- and age-eligible persons identified, 1784 (80 percent) were interviewed.

Physical activity was assessed using a modification of the Lipid Research Clinics study questions on physical activity.[21] Participants who reported engaging in exercise or work strenuous enough to sweat for at least 20 minutes, three times per week, were classified as active. Those who reported exercising or laboring less often, less vigorously, or not at all were classified as sedentary.

Three sitting blood pressure measurements were recorded on each respondent's right arm approximately 15 minutes into the interview. Hypertension was defined by an average diastolic blood pressure (average of second and third readings) of 90 mm Hg or greater or by current use of antihypertensive medication. Other predictors of blood pressure measured in this survey and included in the current analyses were age, body mass index (BMI) in kg/m^2, waist to hip ratio (WHR), and alcohol consumption.[20] Sociodemographic descriptors of the study participants were years of education and employment status. Complete data were available on 1751 respondents in the survey.

Weighted analyses were performed to take into account the sampling strategy as well as nonresponse in making population estimates of prevalence. All analyses were gender specific because of expected male-female differences in physical activity and blood pressure. Logistic regression was used to estimate associations between physical activity and hypertension, adjusting for potential confounding by age, BMI, WHR, and alcohol consumption.[22–24]

Results

The distribution and correlates of physical activity are shown in Table 1. Of the 1751 individuals in the analysis, 285 men (44% of 655 men) and 711 women

Note. β = logistic regression coefficient; SE = standard error; BMI = body mass index; WHR = waist to hip ratio.

(65% of 1096 women) were classified as sedentary. Sedentary adults of both sexes were more likely to be unemployed. A weaker association was observed between sedentary behavior and being a high school graduate. Age, BMI, and consumption of alcohol were unrelated to physical activity. Among men, WHRs were slightly greater among those with sedentary life-styles.

Prevalence of hypertension was higher in the sedentary than in the active women (26.2% vs 20.0%, $P < .01$), but there was no significant difference between sedentary and active men (30.6% vs 31.7%, respectively). These findings persisted (Table 2) after adjustment for age, BMI, WHR, and alcohol consumption. The adjusted odds ratios (95% confidence intervals) were 1.59 (1.14–2.34) and 0.82 (0.57–1.18) for women and men, respectively. The results did not change when education and unemployment were added to the model.

Discussion

In this sample of Black adults, the majority of the women and a sizable minority of the men were classified as sedentary. The difference by sex is consistent with reports from other cross-sectional surveys.[13,15,18,25,26] The overall level (57%) of sedentary behavior in this population of young to early middle-aged adults was higher than expected, nearly equaling the median level (59 percent) observed in the 1987 Behavioral Risk Factor Surveillance System,[27] a survey of 32 states that included older, presumably less active adults.

The prevalence of hypertension was significantly higher in self-reported sedentary adults only among women. A similar difference was reported in cross-sectional findings on blood pressure from the Stanford Community Health Survey,[25] but the results from studies of men and women generally are not consistent with sex-specific effects.[19,28–32] Two possible explanations for the difference in findings for men and women were examined in these data. The association between exercise and hypertension in men could have been biased toward the null if previously sedentary men were especially likely to begin exercising after being diagnosed as hypertensive. However, among hypertensive adults no association was observed between activity and awareness of hypertension, making this form of bias an unlikely explanation for our results. The temporal relation between physical activity and hypertension cannot be determined with complete certainty in these data. A second possibility is that the results for men and women reflect interaction between obesity and activity, with activity being more protective in the presence of obesity, which was far more common in women. This pattern of interaction was reported for Harvard alumni,[33] but was not present in sex-specific stratified analyses of these data. Nondifferential misclassification of activity cannot be evaluated with available data and may have been greater for men than for women.

Most recent surveys have found a direct cross-sectional association between indicators of socioeconomic status and physical activity.[18,34] The weak inverse association between education and physical activity in this population may be a chance finding or may be due in part to job-related activity required of those with less education in Pitt County. The association between unemployment and sedentary behavior is consistent with the notion of work as a source of physical demands or a source of financial means for engaging in leisure activity. However, the overall level of sedentary behavior in this community suggests that increases in physical activity, even among the employed, are needed. The high prevalence of reported sedentary behavior also suggests that an understanding of community-level influ-

ences on exercise and activity may be necessary for successful intervention.[35,36] □

Black-White Differences in Infant Mortality in 38 Standard Metropolitan Statistical Areas

Anthony P. Polednak, PhD

ABSTRACT

The Black–White difference in infant mortality rates for 1982 through 1986 in 38 large US standard metropolitan statistical areas (SMSAs) varied by a factor of almost seven. In multiple regression analyses the most important predictor of the Black–White difference in the 38 SMSAs was an index of Black–White residential dissimilarity (or "segregation index"), independent of Black–White differences in median family income and poverty prevalence. Certain SMSAs in California had relatively low segregation indexes and small Black–White differences in infant mortality, despite considerable Black–White differences in poverty prevalence. The explanations for the apparent effect of residential segregation should be explored. (*Am J Public Health.* 1991;81:1480–1482)

Introduction

The US Black–White difference in the infant mortality rate has persisted. Lower rates have been reported for Blacks in the West than in the other three US census regions.[1] This report examines the Black–White difference in infant mortality rate in 38 large standard metropolitan statistical areas (SMSAs), including several in California, in relation to socioeconomic status indicators and an index of residential segregation. Residential segregation may be associated with such factors as the availability and quality of prenatal and postnatal medical care, which may influence infant mortality independent of differences in socioeconomic status.

Methods

For each of 38 SMSAs with a total population of more than 1 million in 1980, 1980 census reports were used to obtain Black–White differences in poverty prevalence, median family income, and the percentage of families with a "female householder, no husband present."[2] One segregation index (an index of residential dissimilarity between Blacks and Whites in the SMSAs based on 1980 census data) measures the unevenness of residential distribution of a specific minority population across census tracts within an urban area. The formula is as follows:

$$0.5 \times \sum_{i=1}^{n} | (x_i/X) - (Y_i/Y) | ,$$

where x and y are the numbers of each race with a tract (i) and X and Y are the total populations of each race in the SMSA.[3] Numbers of deaths at less than 1 year of age for Blacks and Whites in each SMSA for 1982 through 1986 were used,[4] along with total live births in these years,[5] to obtain an average annual infant death rate (per 1000 live births) for Blacks and Whites in each of the 38 SMSAs.

Results

Infant mortality rates were higher for Blacks than for Whites in all of the 38 SMSAs. The mean Black–White difference was 8.63 per 1000 live births (SD = 3.27), ranging from 2.14 (95% confidence limits [CL] = −0.90 and 5.06) for Anaheim, Calif, to 14.63 (95% CL = 12.31 and 16.95) for Pittsburgh, Pa (see Appendix for detailed data).

The segregation index and the Black–White difference in poverty prevalence for the 38 SMSAs were significantly correlated ($r = .573$, $P < .001$), but this correlation does not indicate strong collinearity, and both variables were included in multiple regression analysis (Table 1). The segregation index was the only statistically significant independent predictor of the Black–White difference in infant mortality rate among the SMSAs, and the only independent variable selected in stepwise regression (not shown). Only for Blacks was the segregation index a statistically significant independent predictor of infant mortality rate in multiple regression analysis (data not shown).

Chicago had the highest segregation index (i.e., .878) and, a Black–White difference in poverty prevalence (i.e., 28.8%) that was higher than the average (i.e., 18.3%), the Black–White difference in infant mortality was also large (i.e., 13.38 per 1000; 95% CL = 12.39 and 14.17). The seven California SMSAs differed considerably in segregation index. Black–White differences in poverty prevalence ranged from 7.8% for San Jose to 16.6% for Sacramento and 17.4% for Riverside; all were

The author is with the Department of Epidemiology and Public Health, Yale School of Medicine. Part of this work was done while he was with the Department of Preventive Medicine, School of Medicine, State University of New York at Stony Brook, NY.

This paper was submitted to the journal October 5, 1990, and accepted with revisions May 28, 1991.

below the average for all 38 SMSAs. Anaheim had the lowest segregation index and the smallest Black–White difference in infant mortality, whereas Los Angeles had the highest segregation index and the largest Black–White difference in infant mortality (Figure 1), despite the similarity in the Black–White difference in poverty prevalence in the two areas (i.e., 9.9% and 8.7%, respectively).

Discussion

The almost sevenfold variation among the 38 SMSAs in the Black–White difference in infant mortality rate and the association with the segregation index (apparently independent of variation in the Black–White difference in poverty prevalence) require explanation. Socioeconomic status may not have been adequately controlled for in the analysis of the effect of the segregation index on the Black–White difference in infant mortality; areas with high segregation indexes may include subareas (in inner cities) of extreme poverty and high cost of living. Potential inaccuracies in infant death rates by SMSA due to differential rates (among the SMSAs) of migration of mothers (with their infants) after birth should be examined by separate analysis of neonatal and postneonatal death rates (both of which are higher in US Blacks than Whites). Neonatal death rates would be little affected by migration, because migration during this period is unlikely. Linked live birth–infant death files also would be useful.

Despite considerable Black–White differences in poverty prevalence, two SMSAs in California (i.e., Riverside and Sacramento) with low indexes of segregation had small Black–White differences in infant mortality (Figure 1). The explanation for low Black infant mortality rates in Anaheim, with both a small Black–White difference in poverty prevalence and a low segregation index, also should be explored. Birth weight distributions, birth weight–specific death rates, and both neonatal and postneonatal death rates should be examined. Binkin et al.[6] suggested that the smaller difference in Black–White neonatal death rates within normal weight births in California than in Georgia could reflect better quality and availability of prenatal, intrapartum, and postnatal care in California Blacks. The need for studies of the quality vs the quantity of prenatal care in Blacks has been recognized,[7] and the same holds for postnatal care. SMSAs with high levels of segregation are mainly large, older industrial cities with Black ghettos.[3] Among the many potential explanations for higher infant mortality rates in these segregated areas, availability (or accessibility) and use of diagnostic/treatment procedures, level of training and attitudes or recommendations of providers, and patient (i.e., maternal) decision making should be examined, as suggested for explaining racial inequalities in use of diagnostic/treatment procedures for cardiovascular disease.[8] □

TABLE 1—Prediction of the Black–White Difference in Infant Mortality Rates (1982–1986) in 38 SMSAs

	Regression Coefficient	*t*	*P* Values
Female householder[a]	−.0672	−.263	.794
Poverty prevalence[b]	.2503	1.524	.137
Median family income[c]	−.1918	−1.054	.299
Segregation index[d]	.7469	4.033	<.001

Comparison of Smoking Habits of Blacks and Whites in a Case-Control Study

Geoffrey C. Kabat, PhD, Alfredo Morabia, MD, PhD, and Ernst L. Wynder, MD

ABSTRACT

Information from Blacks and Whites interviewed in a case–control study of tobacco-related diseases was analyzed to identify explanatory factors for racial differences in smoking habits. Blacks were three times more likely to be light vs heavy smokers. This association did not differ according to such variables as cigarette preference, degree of inhalation, or quitting. The association of race and light smoking was present in both current and ex-smokers. Sociodemographic or smoking-related characteristics do not appear to explain racial differences in smoking habits. Future studies should focus on cultural factors influencing smoking behavior. (*Am J Public Health.* 1991; 81:1483–1486)

Introduction

Incidence rates of tobacco-related cancers, such as cancers of the lung, esophagus, larynx, and oral cavity, are higher in Black than in White Americans.[1] In addition, Blacks are more often current smokers but, on average, smoke fewer cigarettes per day than Whites.[2–8] Blacks also tend to smoke higher tar, higher nicotine, and more mentholated cigarettes than Whites.[5,9,10]

Understanding the causes of racial differences in smoking habits has major public health implications since it determines the best strategy for smoking cessation. Racial differences are apparently not attributable to socioeconomic factors[2] but, to our knowledge, the role of smoking-related factors such as tar level, mentholation, inhalation, degree of habituation, butt length, and quitting has not been examined heretofore.

Methods

Data presented here derive from a previously described hospital-based case–control study of tobacco-related cancers.[11] Briefly, case patients with cancers of the lung, larynx, oral cavity, esophagus, bladder, pancreas, and kidney and first occurrences of nonfatal myocardial infarction were interviewed in 28 collaborating hospitals in eight US cities. At least one control patient with a condition not known to be related to smoking or alcohol was interviewed within 2 months following the case patient's interview. Control patients were matched to case patients on sex, age (+/− 5 years), race, and hospital.

A total of 23 011 case and control patients, of whom 9% were Black, were interviewed between 1980 and 1990. After removal of exclusively pipe and/or cigar smokers (n = 903), 5301 never smokers (8% Black), 9252 current smokers (11% Black), and 7555 former smokers (6% Black) remained for analysis.

The distribution of diagnoses was similar between Black and White case patients. The most common case diagnoses in men were lung cancer (37% of White and Black case patients), myocardial infarction (21% of Whites, 18% of Blacks), oral cancer (13%, 17%), and larynx cancer (7%, 8%). Among control patients, Blacks had a smaller proportion of cancers than Whites, because Blacks are underrepresented in collaborating hospitals with almost exclusively cancer patients.

The study questionnaire contained detailed items on smoking history, including age at initiation; tobacco products (cigarettes, cigars, pipes, chewing tobacco, snuff); up to four cigarette brands, specifying whether filter or mentholated; years of smoking each brand; and, for ex-smokers, the number of years since quitting. Information was also available on inhalation (not at all, slightly, moderately, deeply), how much of the cigarette the subject usually smoked, and how long after waking the subject generally smoked his or her first cigarette of the day (0 through 15 minutes, 16 through 30 minutes, 31 through 59 minutes, 60+ minutes).

A smoker was defined as one who had smoked at least one cigarette per day for at least 1 year. A smoker who had smoked within a year of diagnosis was a current smoker, otherwise an ex-smoker. A "heavy" smoker was defined as a smoker of more than a pack per day (≥ 21 cigarettes per day). Tar level was categorized into low, moderate, and high tar (< 10, 10 through 14.9, ≥ 15 mg/cigarette). Mentholation was categorized into nonmenthol only (those who had never smoked a mentholated brand for at least 1 year), menthol

Note. Control patients were hospital patients with non-tobacco-related conditions. cpd = cigarettes per day.

1 through 14 years, or menthol 15 years or more based on lifetime smoking history.

We present Black–White comparisons in case and control patients to demonstrate that the pattern of differences is not an artifact of the study design. We also determined whether differences in smoking between the two races were present in both current and ex-smokers. We computed the odds ratio (OR) of being a light vs a heavy smoker related to race (Black vs White) and used logistic regression to adjust for confounding variables and to assess multiplicative interaction.

Results

The breakdown of the total study population by case–control status, sex, and race is displayed in Table 1. As in national surveys, the prevalence of current smoking was higher in Blacks. Among current smokers in the control group, Blacks smoked fewer cigarettes per day, tended to smoke higher tar and mentholated cigarettes, and tended to have smoked for fewer years compared with Whites (Table 2). Black men and women were much more alike in terms of amount smoked than were White men and women (Table 2).

Among control patients (not shown in Table 2), Black men were 5.0 (95% confidence interval [CI] = 3.3–7.1) times more likely, and Black women were 2.5 (95% CI = 1.4–6.7) times more likely, to be light smokers. For case patients, the corresponding ORs and 95% CIs were 3.0 (2.6–4.2) for men and 3.0 (2.0–4.4) for women. These associations persisted across strata of age, education, marital status, Quetelet's Index, menthol use, tar level, inhalation, duration of smoking, butt length, and timing of first cigarette.

As shown in Table 3, among male control patients the association of race with light smoking was greater in current smokers (OR = 5.0; 95% CI = 3.4–7.5) than in ex-smokers (OR = 2.5; 95% CI = 1.6–3.7). The interaction was statistically significant ($P = .01$) and was of similar magnitude within strata of age, Quetelet Index, tar level, inhalation, and alcohol. Differences between current and ex-smokers were even stronger among more educated subjects and among smokers of mentholated cigarettes. In these two subgroups, among current smokers Blacks were about 7 times more likely than Whites to be light smokers, but among ex-smokers Blacks were only about 1.5 times more likely to be light smokers. No interaction among smoking status, level of smoking, and race was seen in female control patients (not shown in Table 3).

Discussion

In the present study, more Blacks smoked; however, among smokers, Blacks smoked fewer cigarettes per day than Whites. This pattern was constant across subgroups defined by sex, case–control status, sociodemographic factors,

life-style factors, and smoking behaviors, and is consistent with US survey data.[2,4,6]

Novotny et al. reported that Blacks were less likely than Whites to be heavy smokers, after adjustment for employment status, blue/white collar status, education, and poverty level.[2] Our results are consistent with the latter findings but, in addition, suggest that the larger proportion of light smokers among Black current smokers is not explained by differences in smoking-related factors.

The agreement of our results with National Health Interview Survey data makes selection or recall bias of hospital patients an unlikely explanation.[4,12] However, purchasing power could account for the racial difference in level of smoking. Although, in the present study, Black–White differences persisted within strata of educational level, education may be a poor indicator of socioeconomic status when comparing Blacks and Whites.

Another explanation is that since the proportion of quitters is higher among Whites and since light smokers are more likely to quit,[13] this could lead to an overrepresentation of heavy smokers among White current smokers. Indeed, there is such a phenomenon, but it does not completely explain the observed association of race and smoking habits since Black–White differences persist, even though attenuated, among ex-smokers (Table 3). It is also possible that Blacks are less susceptible to becoming habituated to smoking since they inhale less (Table 2) and have higher mean cotinine levels compared with Whites for a similar level of smoking.[14,15]

In conclusion, smoking-related factors do not seem to explain racial differences in smoking habits. Thus, effective preventive strategies aiming at smoking cessation may require a better understanding of cultural factors that affect smoking, such as the timing of the most "important" cigarettes, whether smoking is engaged in mainly in the company of others, reason for smoking, reason for smoking mentholated cigarettes (where applicable), and degree of satisfaction from smoking. □

TABLE 3—Adjusted Odds Ratios of Being a Light Smoker for a Black Compared with a White, by Smoking Status, in Male Control Patients, 1980–1989

	Current Smokers	Ex-Smokers	*P* value[a]
Overall	5.0	2.5	.01
Age			
< 60 yrs	4.7	2.6	.11
≥ 60 yrs	5.2	2.4	.12
Education			
< 13 yrs	4.3	3.0	.26
≥ 13 yrs	7.1	1.6	.01

Alcohol			
None/occasionally/light	4.1	2.4	.20
Heavy	5.3	2.6	.07

Note. QI = Quetelet's Index. Odds ratios were adjusted for all variables other than the stratifying variable. Variables were categorized as follows: amount smoked (1–20, ≥ 21 cigarettes per day), mentholation (nonmenthol only, menthol 1–14 years, menthol ≥ 15 years), inhalation (deeply, else), timing of first cigarette of the day (≥ 60, < 59 minutes after waking), age (< 60, ≥ 60), education (< 13, ≥ 13 years), alcohol (never/occasionally, ≥ 1 oz whiskey equivalents per day), QI (≥ 28, < 28), smoking duration (< 30/≥ 30 years), portion of cigarette smoked (all, ≤ ¾), and type of hospital. The model also included a variable indicating whether the subject was a current or ex-smoker and a product term between this variable and amount smoked (< 20, ≥ 20 cigarettes per day). Control patients were hospital patients with non–tobacco-related conditions.

[a]Test for homogeneity of the odds ratios between current and ex-smokers.

A 5-Year Follow-up Study of 117 Battered Women

Bo Bergman, MD, DrMed Sci, and Bo Brismar, MD, DrMed Sci

ABSTRACT

This paper reports register data concerning somatic and psychiatric hospital care on 117 battered women who were identified in a surgical emergency department and offered a treatment program. Data were collected during a period of 10 years before to 5 years after the battering in question. It was concluded that the battered woman seeks hospital care much more than the average woman of the same age. It is, however, not only traumatic injuries that bring her to the hospital, but also medical, gynecological, psychiatric, and unspecified disorders and suicide attempts. In this study it was hypothesized that this overuse of hospital care reflects the situation at home characterized by ongoing battering and other psychosocial problems. During the 5 years following the battering, the women did not show any signs of reducing their use of hospital care. It is alarming that this high use of medical care continues over years, and doctors should consider battering as one possible explanation for this phenomenon.(*Am J Public Health.* 1991;81: 1486–1489)

Introduction

During the last few decades, with more and more attention being given to the problem of wife battering, various intervention programs aimed at stopping the battering or otherwise helping or supporting battered wives have been tried.[1–3] However, conclusive information concerning the effect of different intervention programs is sorely lacking.

In this study the use of medical care will be used as an indicator of the general life strain, including battering, under which battered women live. The aim of the study was to investigate the use of somatic and psychiatric hospital care by battered women and to use these data as a model to evaluate the effectiveness of a wife battering intervention program in a medical setting.

Subjects and Method

From November 1983 to June 1984, there was an emergency room project at the Huddinge Hospital, Huddinge, Sweden, that attempted to identify and support battered women seeking hospital care. All women in the emergency room who reported injuries resulting from battering were offered admission to the hospital even if the injuries did not warrant it per se. The women were given supportive counseling by a social worker and, if necessary, they talked to a psychiatrist. They were also offered continued supportive counseling by the social worker after returning home, and, on these occasions, they were provided an opportunity to contact social services, lawyers, and other sources of help.

During the 8-month period in question, a total of 117 battered women sought help in the emergency room. Fifty-eight agreed to enter the treatment program, and 59 went home after routine care. The batterer was the woman's husband, cohabitant, or steady partner (65%); her ex-husband or ex-cohabitant (19%); or a close male relative (16%). The mean age at the time of the battering was 33 ± 2 years (range: 16–75). The battered women were compared with a control group that was selected from the population register and matched with the group of 117 battered women for age and geographic area in Stockholm.

The battered women and the control subjects were studied regarding consumption of somatic and psychiatric hospital care during the period from 10 years before to 5 years after the battering. These data were obtained from the Stockholm County Council's computer files, supple-

This paper was submitted to the journal May 5, 1990, and accepted with revisions April 4, 1991.

mented with data from medical records. The battered women and the control subjects were further compared concerning sociodemographic data collected from the population register. At the time of the follow-up 5 years after the battering, one woman had died (not from abuse, however) and another five had requested confidentiality concerning marital status, address, and nationality. Thus, the study group was reduced to 111 regarding sociodemographic data.

Statistics

For intergroup comparisons, the chi-square or Fisher's Exact Test were used.

Results

Sociodemographic Data

The marital status of the battered women was characterized by a great proportion of divorcées and a small proportion of married women compared with the control subjects (Table 1). These conditions were stable in time. However, there were significantly more changes in marital status among the battered women than among the control group. Table 2 illustrates this higher turnover among the battered women, who went through more divorces than the control subjects both during the 5 years preceding the battering and during the following 5 years. The battered women were also less prone to marry during the interval of time studied.

Somatic Hospital Care

The battered women had a significantly higher consumption of somatic hospital care during the 15-year study period (Table 3). Ninety of 117 battered women (77%) had been admitted to the hospital at least once, compared with 58 of the 117 control subjects (50%). Even more striking was the difference in the number of admissions—420 for the battered women and 119 for the control group. The most pronounced differences were found in the number of admissions due to suicide attempts, for observation (undefined disorders), and due to trauma.

Figure 1 illustrates the considerably higher use of somatic hospital care by the battered women than by the control group in all age ranges except the youngest group. The difference is most pronounced between 30 and 40 and then gradually diminishes.

TABLE 1—Marital Status of Battered Women and Control Subjects at the Time of the Battering and 5 Years Later

***$P < .001$.

Psychiatric Care

The total use of psychiatric care by the battered women during the 15-year period widely exceeded that of the control subjects. A total of 69 battered women had been admitted to a psychiatric clinic during the period in question; only 1 control woman had been admitted, and only on one occasion. Fifty-six battered women had attended a psychiatric outpatient clinic compared with 9 control subjects ($P < .001$).

In Table 4 the spectrum of psychiatric diagnoses concerning inpatients is presented. Substance abuse, suicide attempts, and depression were common. Psychoses were the least frequent major psychiatric diagnostic category.

Total no. of psychiatric inpatients	69	59	1

*$P < .01$.
**$P < .001$.

Treated versus Untreated Group

Half of the 117 battered women entered the treatment program. However, when the two 5-year periods before and after the battering were compared, those who entered the program did not reduce their use of either somatic or psychiatric care.

Discussion

The present study has elucidated the battered woman's exposed situation. The women included in the study were identified in the emergency room when seeking aid for acute injuries, which presented an opportunity for early identification and intervention. However, there could be a question as to whether this way of identifying the subjects produces a study group that is only partially representative of all battered wives. The general impression made by the present study group is that it is more heavily loaded psychosocially with personal problems, including alcohol and drug abuse, than most populations of battered wives described in the literature.[4–6]

There were more divorcées among the battered women than among the control group, and during the 5 years following the battering in question the battered women continued to change their marital status more frequently than the control subjects. These facts reflect the ongoing strife in their marriages. Women who frequently change male partners probably increase their risk of being battered.

The use of somatic hospital care was dramatically higher among the battered women than among the control women. The most impressive difference between the groups concerns repeated periods of care, especially for undefined disorders, suicide attempts, and trauma. These findings are compatible with the description of the "battered wife syndrome" comprising surgical, psychosomatic, and psychiatric symptoms such as depression, headache, insomnia, and anxiety.[7–11] Although trauma is one major diagnostic category in the present study, it is not the most frequent one. This indicates that injury is just one part of a symptom complex that battered wives show. The high use of medical care could be presumed to reflect the degree of ongoing battering in the home quite well. This hypothesis is supported by the results presented in Figure 1, with a peak in use of care in the age range 25 through 39 years. Many studies have found a median age of battered wives of 30 to 35 years,[12–14] with the husband a couple of years older. The risk of being battered seems to be most pronounced in the late 20s and in the 30s.

There was no decrease in use of somatic hospital care by the women who entered the treatment program during the 5-year follow-up period. The use of somatic hospital care was stable at a high level in the entire battered group compared with the controls. The use of psychiatric care also seemed stable at a much higher level than expected. □

Mammography in a Health Maintenance Organization

John P. Hansen, MD, MSPH, Penny A. Knapp, RN, BSN, and Polly A. Newcomb, PhD

ABSTRACT

The charts of a random sample of 496 women, aged 51 and older, in a staff model health maintenance organization (HMO) were retrospectively audited for mammography frequency over an 8-year period. Of the 496 women, 306 (61.7%) had at least one mammogram. For the 422 women who had been members of the HMO for at least 2 years, 196 (46.4%) had mammography within the previous 18 months. (*Am J Public Health.* 1991;81:1489–1490)

Introduction

There is little documentation in the medical literature on the performance level of health maintenance organizations (HMO) in carrying out screening mammography according to recommended guidelines. The purpose of this article is to report the frequency of screening mammography in a staff model HMO.

Methods

A 50% random sample of the female members of a staff model HMO in Madison, Wis (total membership = approximately 26 000), who were at least 51 years old and members of the HMO for at least 1 year as of March 1, 1989, was identified. Women with breast cancer diagnosed prior to any screening in this HMO or diagnosed prior to March 1, 1981, were excluded from the sample. A chart review was conducted on this sample's mammography utilization for the 8-year period from March 1, 1981, through February 28, 1989. The following information was abstracted from the chart: number and dates of mammograms, abnormal findings (defined as those resulting in a recommendation other than routine follow-up in one year), and follow-up studies. Any mammogram obtained within 6 months of a previous mammogram was excluded because it was assumed that it would have been performed as a recommended follow-up exam and not as a routine screening mammogram.

For each member, an expected number of screening mammograms was calculated, based on the member's age or length of membership. The expected number based on age was calculated by subtracting 50 from the age in years as of March 1, 1989. The expected number based on membership duration was the actual length of membership in years. The smaller of the two calculations was the expected number of screening mammograms for the member, with the maximum number expected set at 7.

No special programs, such as patient reminders, were in place to encourage mammography. There were no out-of-pocket costs to the patients for mammography.

Results

A total of 1030 women aged 51 years and older were enrolled in the HMO at the time of the study. An approximate 50% sample of 511 was randomly selected. Fifteen of these women had a previous diagnosis of breast cancer and were excluded; the final sample numbered 496. The mean age of the women was 59.4 years (range = 51–84) and the mean length of membership was 4.7 years (range = 1–13) (Table 1).

Of the 496 women, 306 (61.7%) had at least one mammogram and 78 (15.7%) had all of their expected number of mammograms. During the most recent year of the study, 178 (35.9%) had at least one mammogram. Of the 422 women who had been members for at least 2 years, 196 (46.4%) had a mammogram within the previous 18 months.

Older women were more likely to have had a mammographic examination than were younger women ($P = .034$). In addition, increasing length of membership

TABLE 1—Women with at Least One Mammogram by Age and Length of HMO Membership

Age	Members <4 yrs		Members ≥4 yrs		Total	
	n	Mamm. (%)	n	Mamm. (%)	n	Mamm. (%)
51–55	68	28 (41.2)	88	60 (68.2)	156	88 (56.4)
56–60	53	22 (41.5)	88	66 (75.0)	141	88 (62.4)
61–65	51	25 (49.0)	67	50 (74.6)	118	75 (63.6)
≥66	26	14 (53.8)	55	41 (74.5)	81	55 (67.9)
Total	198	89 (44.9)	298	217 (72.8)[a]	496	306 (61.7)[b]

Note. Mamm. = number of women with at least one mammogram.
[a] χ^2 for the difference in proportion by membership length = 39.1 (1df), $P < .001$.
[b] χ^2 for the difference in proportion by age = 3.37 (3df), $P = .034$.

was strongly associated with mammography ($P < .001$) (Table 1). Of those who were between the ages of 66 and 70 and had been members in the HMO for 4 or more years, 84.6% had at least one mammogram, whereas only 41.2% of those aged 51 to 55 who were members for less than 4 years had mammography during their membership.

Discussion

The intent of this study was to document the frequency of screening mammography in women over age 50 in a staff model HMO. Three recent studies in clinical practices have reported frequency rates of women having mammography in the year prior to the study of 15.6% to 26.6%, in contrast to the 39.5% found in this study.[1–3] We also looked at the frequency of mammography within the past 18 months for women who had been members of the HMO for at least 2 years and found 46.4% of these women had received mammography. In several population surveys, frequency of mammography during the year previous to the survey ranged from 17% to 46%.[4–9] In several studies and surveys reporting the percent of women over age 50 who had ever had at least one mammogram, the frequency ranged from 39.2% to 74.0%, as compared to 61.7% in this study.[1,6–12]

It is somewhat difficult to compare the results in this study with all of the above mentioned surveys because they were conducted in different years and it is clear that the frequency of mammography has been increasing in the last several years.[4,5,12] However, given the time frame of this study, the use of mammography by this HMO compares quite favorably with that reported in the above studies.

In one clinical study,[2] it was noted that 40% of the patients who had HMO insurance had mammography in the previous year in contrast to only 16% of all patients in the study. Several studies have demonstrated an increased use of preventive services and visits by patients enrolled in HMOs compared to other health care systems.[13–16] Whether this is related to the characteristics of the HMO itself or to the reduced financial barrier characteristic of HMOs is unclear, but several other studies have shown that use of preventive services increases as patient out-of-pocket costs decrease.[8,17–19] However, one of the above studies was a well-controlled prospective study that looked at both factors and found that patients in a prepaid system had significantly higher numbers of preventive visits than those in a fee-for-service system, even when there were no out-of-pocket costs for those in the fee-for-service system.[13] It is likely that both the absence of financial barriers and the nature of the managed care system contributed to the observed frequency of mammography utilization in this staff model HMO. □

Geographic Variation in Relative Fees under Medicare

José J. Escarce, MD, AM

ABSTRACT

Little is known about geographic variation in Medicare's relative fee structure. Using 1986 Part B Medicare claims data, ratios among physician fees for surgical procedures belonging to small families of closely related procedures, excluding outliers, were found to vary up to twofold. Under Medicare's current system of physician payment, physicians in different areas face different financial incentives for performing one procedure in preference to possible alternatives. Changes in incentives under a resource-based Medicare fee schedule will be more pervasive than previously recognized. (*Am J Public Health.* 1991;81:1491–1493)

Introduction

Substantial geographic variation in Medicare physician fees has been documented.[1–5] In contrast, little is known about geographic differences in the relationships among fees for different services (i.e., in Medicare's relative fee structure), although recent findings suggest that these differences may be considerable. Researchers have found that fees for different services are not highly correlated across areas,[3] and that areas with high fees for one service often have low fees for other services.[4,5]

Under the Omnibus Budget Reconciliation Act of 1989, a resource-based Medicare fee schedule will be phased in over 5 years beginning in 1992.[6] The fee schedule will impose a uniform relative fee structure in all geographic areas. Therefore, studying existing geographic differences in relative fees can shed light on the extent to which the financial incentives facing physicians will change under the fee schedule. This article describes the geographic differences in the relationships among Medicare fees for surgical procedures belonging to small families of closely related procedures.

Methods

The data for this study were obtained from the 1986 Part B Medicare Annual Data (BMAD) Procedure File. This file contains information on all physician services billed to Medicare, including each service's frequency and total allowed Medicare charges, reported at the level of Medicare charge locality and physician specialty. Services are identified using Physicians' Current Procedural Terminology (CPT) codes.[7]

Seven families of procedures were selected for analysis based on high frequency of use and representation of the principal specialties that provide services to Medicare enrollees (Table 1). Relative fees for the procedures in a family were calculated in three steps. First, each procedure's average allowed charge was determined by charge locality and physician specialty. Claims for assistance at surgery were excluded from these calculations. Second, a "reference" procedure was chosen in the family. (The choice of reference procedure is arbitrary and does not affect the study's findings.) Third, the relative fee for each procedure in each locality was calculated as the ratio of the average allowed charge for the procedure to the average allowed charge for the reference procedure in the family.

All analyses of geographic variation in relative fees were specialty specific. To reduce the influence of infrequent events on the results, the analyses for each family used only data for charge localities where each procedure in the family was performed at least 10 times by physicians in the relevant specialty. (Limiting the analyses to charge localities where each procedure was performed at least 25 times does not affect the findings.) Data for Alaska, Hawaii, and Puerto Rico were excluded.

Results

Relationships among fees for procedures in a family varied considerably across charge localities for all families studied. For the five families of procedures performed predominantly by physicians in one specialty (Table 2), relative fees varied by a factor of 1.25 to 2 even excluding the 5% of localities with the highest and lowest relative fees. Relative fees for knee arthroplasty exhibited the greatest variation. The ratio of the average allowed charge for total knee replacement to the average allowed charge for single compartment arthroplasty was less than 0.89 in 5% of localities where orthopedic surgeons performed each procedure at least 10 times, but it exceeded 1.83 in another 5% of localities. Relative fees for

[a]Number of localities where each procedure in the family was performed at least 10 times by physicians in the relevant specialty.
[b]Relative fee in 5% of charge localities is less than 5th percentile, in 50% of localities less than 50th percentile, in 95% of localities less than 95th percentile.
[c]Reference procedure for calculating relative fees = partial mastectomy; specialty = general surgery.
[d]Reference procedure for calculating relative fees = single compartment arthroplasty; specialty = orthopedic surgery.
[e]Reference procedure for calculating relative fees = coronary bypass with one graft; specialty = thoracic surgery.
[f]Reference procedure for calculating relative fees = transurethral resection; specialty = urology.
[g]Reference procedure for calculating relative fees = intracapsular extraction; specialty = ophthalmology.

cataract extraction with lens insertion showed the smallest variation.

Findings were similar for the two families of procedures performed in appreciable numbers by physicians in more than one specialty. Relative fees for permanent pacemaker insertion varied by a factor of 1.5 to 2 (Table 3). Relative fees for colonoscopy varied by a factor of 1.25 to 1.67 (Table 4).

Discussion

This study documents considerable geographic differences in relationships among Medicare fees for surgical procedures even when the procedures are closely related. These results extend previous findings of large differences in the ratios of the fees for several common but unrelated physician services to the fee for inguinal hernia repair.[8]

The causes of geographic variations in relative fees are unknown. One possibility is that these variations are due to market factors unique to each procedure. However, it seems unlikely that market factors could differ enough among procedures in the same family to account for the large variations found in this study. Another possibility is that the variations are caused by physician pricing decisions that are largely arbitrary and cannot be explained by the usual market forces. Further research is needed in this area.

The findings of this study suggest that physicians in different areas face different financial incentives for providing one procedure in a family in preference to others. Whether these incentives affect physician decision making is unknown. They have potential clinical relevance, however, because for many patients seen in clinical practice, the best choice among procedures in a family may not be clearcut (e.g., partial mastectomy vs modified radical mastectomy) and could be influenced by nonclinical factors. Determining if there is a relationship between geographic differences in relative fees and variations in the use of physician services by Medicare enrollees is an important subject for future research.[9,10]

This study also reveals the extent to which the financial incentives facing phy-

sicians will change under a resource-based Medicare fee schedule. It is widely recognized that the fee schedule will result in higher fees for evaluation and management services and lower fees for most surgical procedures.[6] What has gone unnoticed, however, is that by imposing a uniform relative fee structure in all payment areas, the fee schedule also will lead to innumerable changes in the relationships among fees for different surgical procedures. Some of these changes may be substantial.

The fee schedule, therefore, will not just realign physicians' financial incentives for choosing between evaluation and management services and surgery. In many instances, it may also considerably alter physicians' incentives for choosing among surgical procedures. Evaluating whether these changes in incentives affect patterns of surgical care, including access and appropriateness, should be part of any plan to monitor the impact of Medicare physician payment reform. □

Age- and Sex-Specific Cycles in United States Suicides, 1973 to 1985

Richard McCleary, PhD, Kenneth S. Y. Chew, PhD, James J. Hellsten, MS, and Marilyn Flynn-Bransford

ABSTRACT

Total US suicides peak on the first day of each week, in the first week of each month, and in the late spring of each year. Although these cycles are assumed to characterize all US suicides, analyses by age and sex show that the cycles occur only in a few subpopulations. Day-of-the-week effects are found almost exclusively in middle-aged suicides; day-of-the-month effects are found almost exclusively in elderly male suicides; and month-of-the-year effects are found almost exclusively in teenaged and elderly suicides. (*Am J Public Health.* 1991;81:1494–1497)

Introduction

Analyzing 129 621 US suicides recorded during 1972 to 1978, MacMahon[1] found that (1) within each year, suicides peak in late spring and drop in winter; (2) within each month, suicides peak on the fifth day and drop until month's end; and (3) within each week, suicides peak on Monday and drop to weekend lows. Although all three cycles were reported as early as the 19th century,[2,3] MacMahon confirmed their existence in a reliable data set. Even with a 7-year series (1972 to 1978, 2557 days), unfortunately, analyses of aggregated suicides cannot answer questions of heterogeneity. Analyses of a longer 13-year series (1973 to 1985, 4748 days) confirm MacMahon's basic finding of annual, monthly, and weekly cycles. But more significantly, subpopulation analyses reveal that the cycles vary by age and sex.

Data and Method

To avoid the temporal and geographic limitations of earlier studies,[4,5] individual suicide data for 1973 to 1985 were obtained from a database compiled by the National Center for Health Statistics.[6] Data from 1972 were excluded because they were a 50 percent sample. Otherwise, our data are identical to those analyzed by MacMahon.

Although the magnitude of a time series cycle can be expressed in many ways, the simplest index is the PRE (proportionate reduction in error) statistic for the periodic means. To define this index, let $\bar{S}$ be the mean number of suicides for all (4748) days and let $\bar{w}_i$, $\bar{d}_j$, and $\bar{m}_k$ be the mean number of suicides on the i^{th} weekday, j^{th} date, and k^{th} month. Then for weekdays, dates, and months

$$PRE = 1 - \sum_{t=1}^{4748} \sum_{i=1}^{7} (S_t - \bar{w}_i)^2 / (S_t - \bar{S})^2,$$

i = Sunday to Saturday

$$PRE = 1 - \sum_{t=1}^{4748} \sum_{j=1}^{31} (S_t - \bar{d}_j)^2 / (S_t - \bar{S})^2,$$

j = 1st to 31st

$$PRE = 1 - \sum_{t=1}^{4748} \sum_{k=1}^{12} (S_t - \bar{m}_k)^2 / (S_t - \bar{S}),^2$$

k = January to December

PRE varies between 0 and 1 and is interpreted as the proportion of variance in daily suicides attributable to weekdays, dates, or months.

Results

Table 1 breaks down US suicides by day of the week, date, and month. This longer series confirms MacMahon's finding of weekly, monthly, and annual cycles. We proceed first to disaggregate total periodicity by age and sex and then to disaggregate each of the three cycles—weekly, monthly, and annual—by age and sex.

Table 2 reports PREs for day of the week, date, and month estimated for 15 age groups. Under a null hypothesis, PREs follow an F-distribution with degrees of freedom equal to the series length (n_1 = 4748) and the number of periods (n_2 = 7 days of the week, 31 dates, or 12 months). Null hypothesis probabilities are listed beside each PRE in parentheses. With .01 significance, many of the PREs are due to chance. The PREs are graphed

in Figures 1a through 1d to highlight some striking patterns of significance.

Total Periodicity

Considering all three cycles jointly (Figure 1a), periodicity is more pronounced for male than female suicide. Males younger than 25 and older than 45 appear most affected. Although PREs for females rise between ages 50 and 70, the effect is more striking among males.

Day of the Week

This cycle plays no significant role in either male or female suicides until middle age (Figure 1b). For men, the effect builds dramatically from age 41 to age 55 and then, from age 56 to age 65, drops just as dramatically. For women, the effect is less pronounced but evident nonetheless.

Date of the Month

This cycle is insignificant for males and females until old age (Figure 1c). For males, the effect appears first at age 60 and increases in size until it stabilizes at age 70. For females, the effect occurs only between ages 60 and 70 and, compared to the male effect, is relatively small.

Month of the Year

For women, this cycle is insignificant (Figure 1d). For males, the cycle is limited principally to teenage and elderly suicides. Although both young and elderly male suicides are subject to annual periodicity, the two cyclical patterns are radically different. Figure 2 plots the standardized mean suicides for males under 16 and over 80 years of age. For the younger group, suicides peak in winter and fall to lows in summer. By contrast, suicide among the very old is low in the winter but rises as summer approaches.

Discussion

This investigation used an extended time series (1973 to 1985) to describe the age- and sex-specific periodicity of suicides in the United States. The analysis shows wide variation in the periodicity of suicide rates across ages and between the sexes. First, the analysis not only confirms that periodicity affects primarily male suicide, but also suggests that its effects are most pronounced for males under age 20 and over age 40. Second, concerning the weekly cycle, the analysis goes beyond existing literature in suggesting that the Monday peak holds mainly for men aged about 40 to 65. Third, it reveals that the monthly cycle observed by MacMahon[1] is primarily due to elderly males and, to a lesser extent, elderly females. Fourth and finally, the analysis not only implies that the annual cycle is primarily a male phenomenon, but reveals that male involvement is bimodally distributed by age: young and old but no middle-aged men are affected.

Both bioclimatic and socioeconomic hypotheses have been used to explain suicide cycles.[7–12] Whether bioclimatic or socioeconomic, most hypotheses up to now have assumed that every act of suicide is subject to the same temporal forces. Our analysis shows that this assumption of population homogeneity is not warranted. On the contrary, we find that for most individuals, the risk of suicide is distributed randomly over the week, over the month, and throughout the year. Only for

Note. PRE = proportionate reduction in error; Prob = null hypothesis probabilities.
[a]Due to collinearity, total may be slightly more or less than the sum of day of the week, date, and month.

some individuals—or perhaps, for all individuals at particular stages of the life cycle—is the risk of suicide distributed nonrandomly. Nonetheless, the complex distribution of periodicity suggests that age- and gender-linked contingencies are involved in suicide and that gender and life cycle should be considered in attempting to understand this phenomenon. □

Family Structure and Child Health

Family structure has an important role in determining children's well-being. Accidents, injuries, and poisonings are more likely to occur in disrupted families. Children from divorced or single-parent families have more emotional, behavioral, and academic problems than children living in traditional mother–father families.

The relationship between family structure and a child's health is especially important because so many children live in nontraditional families. In 1988, 61% of all children in the United States 17 years old and younger lived with both their biological parents, 11% lived in a single-parent household with their biological mother who was formerly married to the child's father, 9% lived with a biological mother and a nonbiological father, usually a stepfather, and 8% lived in a single-parent household headed by a biological mother who was never married to the child's biological father (Figure 1). A variety of family arrangements were reported for the remaining children.

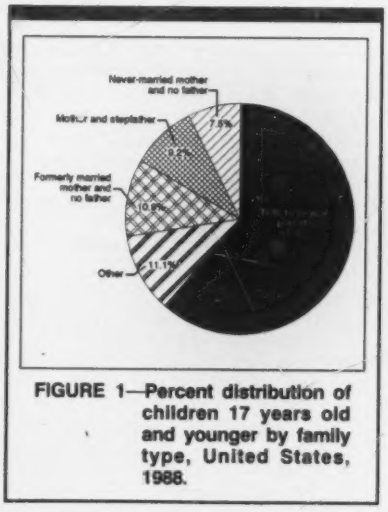

FIGURE 1—Percent distribution of children 17 years old and younger by family type, United States, 1988.

These data are from a new report based on the 1988 National Health Interview Survey on Child Health (NHIS-CH).[1] A description of the NHIS-CH is in the report. The NHIS has been described in this column before and a full description has been published.[2] In brief, the NHIS is a continuing national survey of the health of people residing in households in the United States. For the NHIS-CH, one sample child 17 years old or younger was selected from each family with a child in that age range. Information about the sample child was collected by interviewing the adult member of the family who knew most about the child's health, in most cases the child's mother. Interviews were completed for 17 110 children; the overall response rate was 91%.

Family structure was strongly associated with race and poverty status (Table 1). Children living in two-parent households, whether a nuclear family or a stepfamily, were far more likely to be White than children living in other types of families; children living with a never married mother were far more likely to be Black. Far fewer children in two-parent families lived in poverty than children in single-parent families. The proportion of children living in poverty ranged from 11% of those in a nuclear family and 14% of those living in step-families to 40% of those living with a formerly married mother, and 66% of those living with a never married mother.

Children in disrupted families were more likely to have had an accident, injury, or poisoning within the year before the interview. Children living with formerly married mothers alone or with mothers and stepfathers were more likely to have had an accident, injury, or poisoning in the past year than were other children; 17% and 16% (age-adjusted), respectively, compared with 14% of children overall.

With that exception, there was little variation in children's physical health by family type. Several conditions selected for their association with stress and other emotional problems were examined, but there were inconsistent findings for children with frequent headaches, stammer or speech defects, and bedwetting problems. Asthma was more prevalent among children living in fatherless families than in two-parent families, but the difference was not statistically significant.

However, there was a strong relationship between family type and all the indicators of emotional well-being. The indicators were school performance, rating on a behavior problems index, and treatment for emotional/behavioral problems.

Examination of school performance showed that children in nuclear families had the fewest difficulties in school. Children living with both their biological parents were about half as likely to have repeated a grade in school compared with children in all other types of families. Eleven percent (age-adjusted) of children in nuclear families repeated a grade compared with 20% of children living in stepfamilies or 21% living with a formerly married mother and 30% living with a never married mother. The same patterns were

found for problems requiring a parent–teacher conference and for suspensions or expulsions.

Behavioral problems were assessed by a 32-item index designed to measure antisocial behavior, anxiety/depression, headstrong behavior, hyperactivity, dependency, and peer conflict/social withdrawal. The index showed that children in nuclear families had the lowest scores for behavioral problems. Correspondingly, these children were the least likely to have seen a therapist or counselor about a problem in the previous year.

These data are from 1988 when two out of five children lived in nontraditional families. However, the proportion of children who will live in such families at some time during childhood is much higher. Therefore, the risk for children is higher than it appears from a survey taken at one point in time.

The report presents findings from only one section of the 1988 NHIS-CH. Other reports from the same data set on child care arrangements; health insurance and medical care; developmental, learning and emotional problems; and children's exposure to environmental cigarette smoke have also been published.[3–6] Reports on the incidence of childhood infectious diseases, sources of medical care used by minority children, and the use of medical services by children with special health care needs are forthcoming.

The 1988 NHIS-CH is the second survey on child health included as part of the NHIS. The first child health survey was conducted in 1981. Many of the questions from the 1981 questionnaire were repeated in 1988, including items on child care arrangements; family relationships and mobility; characteristics of the child's birth, including prenatal care, hospitalization, and birthweight; chronic medical conditions; general health habits, including bedtime, sleeping arrangements, and seat belt use; school attendance and performance; and behavioral problems. New items in 1988 addressed children's potential exposure to cigarette smoke both before and after birth; developmental, learning, and emotional problems; and regular sources of medical care. □

The 1988 National Health Interview Survey on Child Health was developed by the National Center for Health Statistics in collaboration with the Center for Chronic Disease Prevention and Health Promotion, Centers for Disease Control; the Bureau of Maternal and Child Health and Resources Development, Health Resources and Services Administration; and the National Institute of Child Health and Human Development, National Institutes of Health.

Ordering Information

Copies of Vital and Health Statistics reports are available from the US Government Printing Office, Washington, DC 20402. Prices are given in the GPO catalogue. For Family Structure and Children's Health by D. Dawson, *Vital and Health Stat.* 10(178), order stock no. 017-022-01136-1. The price is: $2.75.

Copies of Advance Data reports are available without charge as long as supplies last from the Scientific and Technical Information Branch, National Center for Health Statistics, Centers for Disease Control, Room 1064, 6525 Belcrest Road, Hyattsville, MD 20782. Tel: 301/436–8500. Advance Data reports are also published as rapidly as possible in *Vital and Health Stat* 16 for indexing in Index Medicus and sale by GPO.

Copies of public-use computer tapes for the basic NHIS and for most data collected through the data systems of the National Center for Health Statistics are available from the National Technical Information Service, Springfield, VA 22161.

Copies of the public-use computer tapes for special studies based on the National Health Interview Survey are available from the Division of Health Interview Statistics, National Center for Health Statistics, Centers for Disease Control, Room 850, 6525 Belcrest Road, Hyattsville, MD 20782. The price for the 1981 Study of Child Health is $160. The price for the 1988 NHIS-CH is $200. Tel: 301/436–7087.

Survey Identifies Physicians Who Manage Home Care Patients

In a recent national survey conducted by Business Mailers, Inc (BMI), a leader in healthcare information lists and databases, the company identified physicians who manage home health care patients. The study concluded that more than 31 000 doctors across all specialties oversee home health care patients.

"With so many medications being offered over the counter, consumers today are more aware of the treatments that are available to them. They are becoming more comfortable with the concept of self-care," says Mike Casey, Product Manager at BMI.

Home health care, a $1.5 billion industry, is one of the fastest growing segments in the medical field. Studies indicate that home health care is escalating at a rate of 30% per year. "This is due to such factors as the high cost of hospitalization, increasing technology, and the propensity toward self-care," says Casey.

According to BMI's study, the most commonly prescribed types of home health care are as follows: skilled nursing, unskilled nursing, home infusion therapy, and respiratory therapy.

BMI can also identify the specific types of infusion therapy (i.e., intravenous antibiotics, chemotherapy) prescribed by physicians who responded to the survey.

BMI's study also indicated that a significant amount of home health care is related to the treatment of such diseases as AIDS and cancer. It also showed the more than 17% (34 000) of the 200 000 physicians who responded treat AIDS patients, and more than 58% (111 000) treat cancer patients.

BMI also surveys doctors to determine their patient volume, prescribing patterns, over-the-counter recommendations, surgical procedures, and diagnostic test ordering frequency. The Treatment Oriented Profiles (TOP/s) database contains information on more than 240 000 physicians.

BMI's new list of doctors who manage home health care patients is available today. To obtain the list, call 1-800-888-8717 (Midwest), 1-800-524-2751 (East Coast), or 1-800-242-5478 (West Coast).

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 Fifteenth St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Michel A. Ibrahim, MD, PhD, Editor, *American Journal of Public Health,* 1015 Fifteenth St., NW, Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication and are not under consideration elsewhere.

Subscription price, individual, is $80/year US, $120/year international; **institutional,** $160/year US, $240/year international. Single copies $10 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 Fifteenth St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters.

Advertising Sales: Mary Beth Kammann, Advertising Manager, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Injury-Related Medical Care Utilization in a Problem Drinking Population

James O. Blose, MPP, and Harold D. Holder, PhD

ABSTRACT

Background. Population-based data on the overall risk of injury among problem drinkers are extremely limited.

Methods. We conducted an eight-year study of injury-related medical care utilization for a group of problem drinkers (n = 3 729) enrolled in the health insurance plan of a large manufacturing firm with plants in a number of midwestern states. A comparison non-problem drinking cohort matched on age, gender, and number of years of enrollment with the same company plan was also utilized.

Results. Problem drinkers utilized injury-related medical care at a rate 1.6 times that of the comparison group and experienced injury-related medical care costs which were three times as high. Increased risks were found for both men and women and for all ages studied.

Conclusions. This study is one of the few to examine the overall incidence of fatal and non-fatal injuries among a large population of problem drinkers and provides evidence that higher medical care costs are associated with chronic alcohol use. (*Am J Public Health* 1991;81:1571–1575)

Introduction

The role of injuries as a public health problem and as a contributor to medical care costs among the general population has seen increasing attention.[1,2] The association of alcohol use with accident and injury has also been the subject of frequent investigation. Yet there is surprisingly little epidemiological data regarding the overall risk of injury—and the attendant utilization of medical care—among alcoholics and problem drinkers.

A considerable body of research has examined the relationship between alcohol use and fatal injuries. (See reviews by Smith and Kraus,[3] Howland and Hingson,[4,5] Hingson and Howland.[6]) The association between alcohol and traffic fatalities has received particular scrutiny.[7,8] On the whole, this research suggests that there is indeed a link between alcohol and fatal injury, although the actual magnitude of the risk cannot be estimated with great precision.

Fatal injuries, however, constitute only a small portion of all injuries.[2,9] The connection between alcohol and nonfatal injuries has received much less attention. Most research on nonfatal injuries focuses solely on traffic accidents.[10,11] Other studies of nonfatal injuries (i.e. those not limited to traffic accidents) are entirely event based—that is, they are based on the analysis of data from accident victims presenting themselves for care at specific facilities such as emergency rooms.[12–17]

While these event-based studies provide important data on the association between drinking and injury, they provide us with little information on the overall incidence of nonfatal injuries among problem drinkers as a group. Roizen[18] reviewed the literature through 1979 and found no studies on nonfatal accidents (other than traffic accidents) which were based on populations of problem drinkers or alcoholics. Our review of the more recent literature has likewise revealed no such studies.

Several national studies of self-reported alcohol-related problems have been published (e.g. Hilton and Clark[19]). The single survey-based study reporting specific data on nonfatal injuries (Hingson, *et al.*[20]) found that high levels of typical alcohol consumption were associated with a higher level of accidental injury in employee populations in four New England states. Such surveys, however, cannot identify diagnosed problem drinkers and alcoholics.

Methods

This study derives estimates of the incidence of medical care utilization due to injury for a problem drinking population. Health insurance claims and enrollment data from a large midwestern manufacturing corporation were analyzed for the years 1974 through 1987. The data base included approximately 20 million health care claims filed by the 260,000 enrollees covered during the 14-year period.

For the 1980–87 period over which ICD-9 (International Classification of Diseases, 9th Revision) codes were available, 3,729 individuals received a diagnosis in-

Address reprint requests to James O. Blose, MPP, Pacific Institute for Research and Evaluation, 121 West Rosemary Street, 2nd floor, Chapel Hill, NC 27516. Dr. Holder is with the Prevention Research Center, Pacific Institute for Research and Evaluation, Berkeley, CA. This paper, submitted to the Journal May 24, 1990, was revised and accepted for publication January 23, 1991.

TABLE 1—Injury-related Medical Care: Average Annual Number of Events, Cost and Inpatient Days for Problem-drinking Group and Matched Group

Number of Injury-Related Medical Care Events	Problem Drinkers N = 3729	Matches N = 3729	P Value[a]	Risk Estimate[b]
All events	1.32 (±.08)	.76 (±.06)	.002	1.74
Inpatient admissions	.04 (±.004)	.01 (±.002)	.001	4.00
Outpatient visits	1.05 (±.07)	.65 (±.06)	.002	1.62
Emergency room admissions	.23 (±.01)	.10 (±.01)	.001	2.30
Total Cost of All Injury-Related Medical Care Events[c]	$250 (±26)	$82 (±11)	<.001	3.05
Average Number of Injury-Related Inpatient Days	.32 (±.03)	.08 (±.04)	<.001	4.00

Annual averages per person, 95% confidence intervals in parentheses.

dicating a chronic drinking problem.* A group of non-problem drinking individuals, i.e. individuals who had never received a diagnosis indicating a chronic drinking problem, was selected from the total enrollee population. These individuals were matched on a one-to-one basis with members of the problem drinker group on age, gender, and the number of years enrolled. The average age of both groups was 38.6 years of age; 75.5 percent of each group was male.

Coverage under the company's broad health insurance policy was quite stable due to the largely unionized nature of the workforce and to the fact that the company's program was self-insured and administered throughout the 14-year period. Company-sponsored HMO options were established in the early 1980s, with benefit provisions similar to the fee-for-service plans. Utilization records for the two major HMOs were available while records for a third HMO were not. Further details on the company's insurance coverage and data base are described elsewhere.**

The diagnosis codes from the Clinical Modification of the 9th Revision of the International Classification of Diseases[21] were used to classify events as injury-related or non injury-related. Events carrying a diagnosis of 800–995 (the injury and poisoning grouping) were classified as injury-related. The supplementary codes for classification of external causes of injury and poisoning were not available. Among the problem drinking group, 9.1 percent also exhibited evidence of the abuse of other drugs—ICD-9 diagnoses of drug psychoses (292), drug dependence (304), or drug abuse (305.2–305.9).

For the two study populations (total N = 7,458) over 50,000 injury-related medical care events (admissions and/or visits) were identified during the 1980–87 period. Measures were developed for inpatient, outpatient, and emergency room events. Each visit or admission was considered a separate event. The actual number of unique injuries cannot be ascertained from the data, nor can events related to fatal and nonfatal injuries be readily distinguished. No data were available on whether drinking immediately preceded a given event.

Data were also available on the total cost (defined as total charges) for injury-related medical care events. The Medical Care Index (US Department of Labor) was used to adjust all dollar values (reported in December 1985 dollars) for inflation.

All annual averages were calculated based upon the number of months of enrollment (months of exposure) for each individual. Individuals who switched into the HMO plan for which data were not available were considered to have lost their enrollment eligibility at that point. On average, 49 percent of all injury-related medical care events occurred prior to the initial problem-drinking diagnosis, while 51 percent occurred afterward. The average length of enrollment was about six years, approximately equally divided into pre- and post-diagnosis periods.

One class of injuries is underrepresented in the data base. On-site medical staff at major company worksites generally provide medical care for minor on-the-job injuries. No insurance claims are filed if all care is provided on site by company medical personnel. Medical care for work injury was included in our data only if off-site medical services were used.

Selection bias could occur if the manner in which study group members are chosen has a differential impact on the dependent measures for the two groups. Selection into the problem-drinking group is dependent on receiving a specific chronic disease diagnosis while membership in the control group is not. Since the dependent measures used for both groups included injury-related medical care only, selection bias is most likely if a chronic drinking diagnosis is directly associated with an injury-related event. However, only 7 percent of all problem drinkers received any injury-related medical care in the month preceding their initial problem-drinking diagnosis. Thus, there is no evidence that a significant selection bias exists for the study groups used in the analyses reported here.

Results

Table 1 presents the average incidence rates for injury-related medical care events over the 1980–87 period. Problem drinkers averaged 1.32 medical care events per year compared to only .76 per year for those with no chronic drinking diagnosis. The difference between the two groups is especially pronounced for events involving hospitalization. For both groups, injury-related outpatient care events far outnumber emergency room and inpatient admissions. The problem-drinking group also experienced significantly higher injury-related medical costs than did their matched cohort—an average of $250 per year compared to $82. The number of injury-related inpatient days (number of days of hospitalization due to injury) was .32 and .08 per year for the two groups, respectively.

The incidence of injury-related medical care utilization among problem drinkers exceeds the incidence for matches for all

*The following ICD-9 codes were used[21]:
291 —alcoholic psychoses
303 —alcohol dependence syndrome
305.0—alcohol abuse
357.5—alcoholic polyneuropathy
425.5—alcoholic cardiomyopathy
535.3—alcoholic gastritis
571 —chronic liver disease and cirrhosis
572.3—portal hypertension

**Holder HD, Blose JO: The reduction of health care costs associated with alcoholism treatment: A 14-year longitudinal study. J Stud Alcohol (in press).

demographic subgroups examined (Table 2). All differences were statistically significant. Males have much higher injury care rates than females in both groups. The highest injury rates occurred among those ages 31–50, while those age 51 and over showed comparatively low rates of injury.

Both male and female problem drinkers incur annual injury-related medical care costs which are three times the cost of their matches (Table 3). For all subgroups, the risk estimates for costs (Table 3) exceed those for total injury events (Table 2). This may be due to a higher incidence of severe injuries among problem drinkers or to variations in the type of injury. No data are available on these factors.

Adjusting for Demographic Differences between Groups

While the problem drinker and non-problem drinker groups are matched on age, gender, and length of enrollment, other demographic differences between the groups exist (see Table 4). Analysis of variance was used to control for the impact of these demographic factors on the total number of injury-related medical care events. Demographic control variables include GENDER, AGE (30 and under, 31–50, and 51 and over); work class (WORKCL), whether an individual is a salaried or hourly employee; PERSTYPE (i.e. whether an individual is an employee, spouse, child); insurance plan type (PLANTYPE). GROUP denotes whether an individual is in the problem drinking or matched group. All independent variables except gender were statistically significant and were thus included in the final model (Table 5). No interaction terms were statistically significant. The model indicates that after the impact of demographic variables is considered, the difference in injury-related medical care utilization between problem drinkers and matches is still statistically significant ($p = .002$).

Overall, the adjusted level of injury-related medical care events for problem drinkers is 1.6 times what would otherwise be expected (Table 6). While female problem drinkers experience a lower overall level of injury-related care utilization than males, their relative risk is somewhat higher (1.91 vs 1.54). Similarly, problem drinkers over age 51 experience the lowest incidence but the highest relative risk (2.12).

TABLE 2—Average Annual Number of Injury-related Medical Care Events by Gender and Age

	Problem Drinkers	Matches	P Value[a]	Risk Estimate[b]
Gender				
Male	1.46 (±.09)	.82 (±.07)	<.001	1.78

Discussion

This is a unique population-based study comparing overall injury rates among problem drinkers and a matched age and gender cohort. During the eight-year period from 1980–87, the average number of injury-related medical care events per year for over 3,700 problem drinkers exceeded that for the matched group for both males and females and for all age groups. Relative risk estimates range from 1.54 for males to 2.12 for those age 51 and over, based on an analysis of variance model which adjusts for differences due to person type, work class, and insurance plan type. These findings provide clear evidence that the number of medical care events due to injury is significantly higher for problem drinkers than for demographically similar individuals who do not have a known history of problem drinking.

TABLE 5—Final Analysis of Variance Model

	Sum of Squares	DF	Mean Square	F Ratio	P
GROUP	318.84	1	318.84	65.48	.002

30 and under	1.29	.78	1.65
31–50	1.58	1.07	1.48
51+	.91	.43	2.12

[a]Adjusted mean number of injury-related medical care events per year, based on ANOVA results.
[b]Ratio of observed to expected.

This study could not provide direct information on the actual risk of injuries among problem drinkers since the data contained information only on medical care, and not on specific accidents or injuries. In fact, our estimates of the number of injury-related medical events (1.32 per year for problem drinkers; .76 for matches) are significantly higher than rates of self-reported injury reported by survey-based studies of the general population. Hingson, *et al*,[20] in a survey of 1,740 employed adults in New England, found a self-reported annual rate of .22 injuries per person. Data from the National Health Survey[22] indicate a per person annual rate of injury of .38 for persons ages 17–44 and .22 for persons over age 44.

There are several possible reasons for this difference. First, some injuries undoubtedly result in more than one episode of medical care, particularly in cases of serious injuries where extensive follow-up care may be required. Secondly, the number of self-reported injuries may be an underestimate of the actual number. How accurately survey respondents report injuries (usually defined as injuries requiring medical attention) occurring over the course of a year is not clear.

In the end, the observed differences between our problem drinking and nonproblem drinking groups are consistent with other research. Hingson, *et al*,[20] found that persons whose self-reported intake of alcoholic beverages averaged five or more drinks per day had a relative risk of self-reported accidental injury of 1.7, compared with abstainers. This is quite similar to our estimate of the relative risk of injury-related medical care for problem drinkers (1.61).

Our results clearly imply that problem drinkers have either higher overall rates of injury, injuries which are more serious, or both. It is possible that the increased risk among problem drinkers is not due solely to their higher rate of alcoholic beverage consumption. Heavy drinkers may, for instance, be more likely to engage in activities which pose a greater risk of injury. It is also possible that the chronic use of alcohol impedes the process of recovery from physical injury. Additional research will be required to identify the role of these factors.

These findings provide important evidence that higher cost and utilization of medical care related to injury is associated with chronic alcohol use, supporting the view that prevention and treatment of alcohol abuse may be an important approach to reducing injury costs. □

Jenny Labalme, Anniston Star *Medical Writer, Wins 21st Annual Ray Bruner Science Writing Award*

Jenny Labalme, Medical Writer for the *Anniston Star,* is the 1991 recipient of the Ray Bruner Science Writing Award, which is given annually by the American Public Health Association. Labalme was chosen for her strong investigative skills, her sense for important issues, her thorough and thoughtful coverage, and her ability to combine compassion with objectivity.

In a series of several articles, Labalme investigated length-of-stay issues at the psychiatric unit of Anniston's Regional Medical Center (RMC). Former and current employees charged that the clinic kept patients the maximum number of days their insurance would cover regardless of medical need. Labalme's stories spurred still ongoing investigations by Medicare and Blue Cross/Blue Shield. "Jenny wrote these stories before ABC's Prime Time Live followed with a similar series on other psychiatric units run by the same organization elsewhere in the nation," said Joe Distelheim, Executive Editor of the *Anniston Star.*

Since Labalme reported on the alleged insurance milking at the local RMC, Psychiatric Institute, which operates the local clinic in conjunction with RMC, has come under scrutiny by the national media and law enforcement agencies in at least three other states, with particularly serious charges of fraud being investigated in Texas.

In another of her winning entries, a story on pesticides, Labalme provided detailed information on the hazards of the 10 most widely used household pesticides and the need for more aggressive involvement by the EPA. A story on Lay Lake carefully examined the issues surrounding a state health department's announcement to lift a ban on dioxin-tainted fish. According to Distelheim, Labalme's stories on the state's first rural AIDS clinic and the medical community's struggle to deal with their own ambivalent feelings toward AIDS patients has "stirred debate and soul-searching" among the 34,000 readers of the *Anniston Star.*

A panel of five distinguished judges selected the winner for this year's Bruner Award: Tim Friend, Health/Science Editor, *USA Today;* Maureen Mylander, Medical Editor/Writer for NIH's Office of Communications and author of *The Healthy Male—A Comprehensive Health Guide for Men;* Ronald J. Sanchez, Editor, *American Medical Writers Association Journal;* Lynn Wagner, Washington Bureau Chief, *Modern Healthcare;* and Emanuel Landau, PhD, Scientific Consultant, American Public Health Association.

The Ray Bruner Science Writing Award was established in 1971 to recognize outstanding achievement in news reporting by young journalists in the health/science/medical reporting field. It is administered by the American Public Health Association and sponsored by Lederle Laboratories, a division of American Cyanamid Company.

The award commemorates Ray Bruner, a former science editor of the *Toledo Blade* (Ohio), who dedicated much of his time during his 40-year career to encouraging young journalists to enter and excel in the science writing field.

HIV Infection, Genital Ulcer Disease, and Crack Cocaine Use among Patients Attending a Clinic for Sexually Transmitted Diseases

Keith Chirgwin, MD, Jack A. DeHovitz, MD, MPH, Stephen Dillon, MD, and William M. McCormack, MD

ABSTRACT

Background. Recently there has been a rise in genital ulcer disease (GUD) in urban minority heterosexuals in the United States. The impact of these increased GUD rates on HIV transmission patterns in this population is unknown.

Methods. Sexually transmitted disease (STD) diagnoses were correlated with HIV antibody status and risk factor history in 194 patients who consented to HIV testing at an STD clinic in central Brooklyn.

Results. Of 36 HIV-positive patients, 23 (64%) denied HIV risk factors other than heterosexual contact with persons of unknown HIV status. HIV antibody was associated with GUD (odds radio [OR] = 2.72, 95% confidence interval [CI] = 1.20–6.24), multiple concurrent STDs (OR = 2.51, 95% CI = 1.08–5.81), and a history of crack cocaine use (OR = 2.98, 95% CI = inexact–9.61). Crack use was also associated with GUD (OR = 15.15, 95% CI = 3.27–inexact) and multiple simultaneous STDs (OR = 13.87, 95% CI = 4.62–inexact). In a log-linear model analysis, HIV infection was independently associated with GUD and crack use. HIV infection, genital ulcer disease, and crack cocaine use were more common in women than men.

Conclusions. The association between HIV infection and GUD seen here may be secondary to high-risk sexual behavior, which in turn may be partially attributable to crack cocaine use and drug-related prostitution. The high rate of coinfection with HIV and GUD raises a concern about the increased efficiency of sexual transmission of HIV in this population. (*Am J Public Health.* 1991;81:1576–1579)

Introduction

During the last decade divergent patterns of human immunodeficiency virus (HIV) transmission have been noted in different geographic regions. In North America, HIV transmission has occurred primarily in male homosexuals and intravenous drug users (IVDUs). Studies of heterosexual transmission in the United States have suggested a low efficiency of transmission,[1] while the rate of heterosexual transmission of HIV in Africa appears to be much higher.[2,3] Retrospective and prospective studies suggest that this difference may be related at least in part to the higher prevalence of genital ulcer disease (GUD) in Africa.[3–5] Evidence that GUD may increase the risk of acquiring HIV has also been noted in at least one sexually transmitted disease (STD) clinic population in the United States.[6]

Since 1986 the incidence of primary and secondary syphilis in the United States has been increasing, especially in urban minority heterosexuals.[7] In Brooklyn, this trend has encompassed other etiologies of GUD as well. Between 1986 and 1988, cases of primary and secondary syphilis increased 98% (from 589 to 1165), chancroid cases increased 105% (from 556 to 1140), and herpes simplex genital ulcers increased 78% (from 324 to 577).[8] In the STD clinic at Kings County Hospital in Brooklyn, the number of cases of GUD more than tripled from 1986 to 1988 and by the first half of 1989, 35% of STD clinic visits were for GUD.

The impact of this dramatic rise in GUD on HIV transmission patterns in this population remains to be seen. Because this increase has been relatively recent and the incubation period for symptomatic HIV disease is several years, any resulting shift in the risk factor categories of patients reported with AIDS will not become apparent for several years. In this retrospective study, STD clinic visit diagnoses were correlated with HIV antibody status and HIV risk factor history.

Methods

This study took place at a municipal hospital–based STD clinic serving an urban minority population. Confidential HIV counseling and testing with written informed consent have been offered to STD clinic patients since October 1988. HIV risk behavior history was obtained at the initial visit by trained interviewers using a standard questionnaire and also during the follow-up visit when test results were given to the patient. HIV antibody testing was performed by the New York City Department of Health Retrovirology Laboratory. Positive enzyme immunoassay results were confirmed by Western blot.

STD clinic records of patients who underwent HIV testing from October 1988 through February 1989 were retrospectively reviewed to determine STD diagnoses. Primary and secondary syphilis were diagnosed by darkfield examination

Editor's Note. See related Editorial by Hinman on page 1557.

or direct monoclonal immunofluorescent staining for *T. pallidum* or by serology (rapid plasmin reagin confirmed by fluorescent treponemal antibody-absorbed) with compatible physical findings. Chancroid was diagnosed by culture or characteristic gram stain morphology. Specimens cultured for *Hemophilus ducreyi* were inoculated onto Mueller-Hinton medium with 5% chocolated horse blood and gonococcal agar base with bovine hemoglobin and fetal calf serum.[9] Herpes simplex was diagnosed by viral culture (specimens inoculated into A549 and human neonatal kidney cell lines) or direct immunofluorescent staining.

Except where noted, Cornfield confidence intervals and Mantel-Haenszel χ^2 tests were used in calculations of statistical significance. Log-linear model analysis was performed using SPSS statistical software (SPSS, Chicago, Ill).

Results

During this 5-month period, 513 new patients were seen and records were available for 194 who consented to HIV testing. HIV risk factor and demographic characteristics of HIV seronegatives and seropositives are listed in Table 1. Twenty-three of 36 HIV seropositives (64%) denied risk factors other than heterosexual contact with persons of unknown HIV status.

Twenty-four (67%) of 36 HIV seropositives presented with GUD (Table 2). Conversely, 24 of 91 (26%) patients with GUD were seropositive for HIV. GUD was associated with HIV seropositivity (odds ratio [OR] = 2.72; 95% confidence interval [CI] = 1.20–6.24; $P < .01$).

Herpes simplex was the only genital ulcer pathogen in 5 (21%) of 24 HIV-positive genital ulcer patients and could conceivably have been increased in this group due to HIV-related immunosuppression. When genital ulcers due to herpes simplex were excluded from analysis, the association between HIV infection and GUD persisted (OR = 2.82; 95% CI = 1.14–7.03; $P < .02$). In six patients who presented with genital ulcers, the etiology of the ulcer was not determined. All but one of these individuals were HIV seropositive.

Two or more concurrent STDs (not including HIV) were diagnosed in 46 patients. Fourteen (30%) of 46 patients with multiple STDs were HIV seropositive compared with 22 (15%) of 148 patients with fewer than two STD diagnoses (OR = 2.51; 95% CI = 1.08–5.81; $P < .02$).

TABLE 1—HIV Seroprevalence by Demographic Characteristics and HIV Risk Factor.

Characteristic	HIV Seropositive n = 36 (%)	HIV Seronegative n = 158 (%)
Median age (years)	28	26
Sex		
Female	26 (72)	79 (50)*
Male	10 (28)	79 (50)

Hispanic	5 (14)	17 (11)
White	0	4 (2)
HIV risk factor		
Intravenous drug use	9 (25)	4 (3)
Male homosexual	2 (6)	1 (1)
Heterosexual partner known to be HIV infected	2 (6)	2 (1)

*$P < .02$.

TABLE 2.—HIV Seroprevalence by Genital Ulcer Diagnosis

Diagnosis	All STD[a] patients N = 513	No. of patients (%) consenting to HIV testing n = 194	HIV antibody positive (%) n = 36
Primary and secondary syphilis	101	45 (23)	9 (25)
Herpes simplex	48	32 (16)[b]	8 (22)
Chancroid	34	26 (13)[c]	3 (8)
Genital ulcers of uncertain etiology	18	6 (3)	5 (14)
All genital ulcers[d]	183	91 (47)	24 (67)*
Nongenital ulcer diagnosis	330	103 (53)	12 (33)

[a]STD = sexually transmitted disease.
[b]Herpes simplex diagnosed by viral culture and direct immunofluorescent staining in 17, by culture alone in 11, by direct immunofluorescent staining alone in 4.
[c]Chancroid diagnosed by culture and gram stain in 14, culture alone in 4, gram stain alone in 8.
[d]In 18 patients more than one etiologic agent for genital ulcer disease was identified; as a result, number of patients with genital ulcer disease is less than number of genital ulcer diagnoses.
*Odds ratio = 2.72, $P < .01$.

A history of using crack cocaine, a freebase form of cocaine which can be smoked, was noted in 23 patients (18 women, 5 men). Twenty-one (23%) of 91 patients with GUD admitted to crack cocaine use compared with 2 (2%) of 103 patients without GUD (OR = 15.15; 95% CI = 3.27–inexact; $P < .001$). Seventeen (37%) of 46 patients with multiple concurrent STDs admitted to crack cocaine use compared with 6 (4%) of 148 patients with less than two STDs (OR = 13.87; 95% CI = 4.62–inexact; $P < .001$). Two or more etiologies of GUD were diagnosed concurrently in 9 (39%) patients admitting to crack use, compared with 9 (5%) patients without a history of crack use (OR = 11.57; 95% CI = 3.51–38.78; $P < .001$, Fisher's exact).

Six (26%) of the 23 patients with a history of crack use were seropositive for HIV (4 women, 2 men). All six patients denied usual HIV risk factors including intravenous (IV) drug use. Five of these six patients presented with genital ulcers, and the sixth with an oral ulcer. The association between HIV infection and crack use was not statistically significant unless patients with recognized risk factors for HIV (e.g., a history of IV drug use, homosexuality, or a sexual partner known to be infected with HIV) were excluded from analysis. When patients with recognized HIV risk factors were excluded, the HIV seroprevalence rates for patients with and without a history of crack use were 26% (6 of 23) and 11% (16 of 151) (OR = 2.98; 95% CI = inexact–9.61; $P < .05$, Fisher's exact). Similarly, when those with recognized HIV risk factors were excluded from analysis there were increases in the association of HIV

TABLE 3—HIV Infection, History of Crack Cocaine Use, Genital Ulcer Disease, and Multiple Concurrent STDs in STD Clinic Patients without Recognized HIV Risk Factors

HIV Serostatus	Crack Cocaine Use	No. of Patients	No. (%) with GUD	No. (%) with >1 STD
Positive	Yes	6	5 (83)	4 (67)
Positive	No	17	11 (65)	6 (35)
Negative	Yes	16	15 (94)	13 (81)
Negative	No	135	48 (36)	17 (13)
Totals		174	79 (45)	40 (23)

Note. GUD = genital ulcer disease; STD = sexually transmitted disease.

with GUD (OR = 3.68; 95% CI = 1.23–11.29; $P < .01$) and with multiple concurrent STDs (OR = 3.10; 95% CI = 1.13–8.49; $P < .02$). Log-linear model analyses were performed with the following variables: HIV infection, GUD, multiple concurrent STDs, and crack cocaine use (Table 3). Those with recognized HIV risk factors were excluded from analysis. In the model, HIV infection remained independently associated with GUD and crack cocaine use. The association between HIV infection and multiple concurrent STDs, however, depended on the association of each with crack use.

The rate of HIV infection in women was more than double that in men (25% vs 11%: OR = 2.60; 95% CI = 1.11–6.22; $P < .02$). Women were more likely than men to have GUD (OR = 2.28; 95% CI = 1.23–4.26; $P < .006$), multiple concurrent STDs (OR = 2.07; 95% CI = 0.98–4.40; $P < .04$), and history of crack use (OR = 3.48; 95% CI = 1.15–inexact; $P < .02$).

Discussion

In this inner-city, predominantly heterosexual STD clinic population the rate of HIV infection among clients tested was 19%. The majority of HIV-infected individuals denied usual risk factors for HIV such as IV drug use, homosexuality, bisexuality, or having sexual partners known to be infected with HIV. HIV infection was associated with female sex, crack cocaine use, GUD, and multiple concurrent STDs. With log-linear regression analysis, HIV infection remained independently associated with GUD and crack cocaine use.

A similar trend of increased HIV seropositivity in those presenting with GUD in New York City has been described by others.[10] In a city-wide study involving approximately 8600 STD clinic patients in 1988, 13% of those presenting with genital ulcers were seropositive for HIV compared with an 8% overall HIV seropositivity rate.[10]

The time interval to seroconversion for HIV exceeds the usual incubation period for most GUD and therefore HIV infection probably preceded the presenting genital ulcer in most of these individuals. One possibility is that immunosuppressed HIV-infected source partners are at increased risk of developing persistent or recurrent genital ulcers. If this is true, someone who acquires GUD may be more likely than someone who acquires another STD to have been exposed to an immunosuppressed partner with HIV infection. Since HIV transmissibility appears to increase with immunosuppression, such source partners may be more likely to have transmitted HIV even prior to the development of GUD. Another possibility is that genital ulcers may be a direct manifestation of HIV disease.[11] Finally, the explanation for the association between HIV infection and GUD seen in these patients may be that both are dependent covariables of sexual behavior that occurs in milieus where both HIV infection and genital ulcers are common. One such setting may be "crack houses," retail distribution points for crack cocaine where drug-related prostitution is reported to be common.

The rising incidence of syphilis in urban minority populations has been ascribed to a variety of factors, including funding cutbacks in STD control programs, increasing use of spectinomycin (which is not active against incubating syphilis) for the treatment of gonorrhea in areas where beta-lactamase–producing gonorrhea are prevalent, and the recent epidemic of crack cocaine use.[12] Crack cocaine use may be associated with high-risk behavior such as decreased selectivity in sexual partner choice and increased participation in unsafe sexual practices.[12–15] Drug-related prostitution, i.e., sex in exchange for drugs or for money to purchase drugs, may play a critical role in this association.[13,14] In one recent study the association of syphilis with cocaine use persisted after adjusting for number of sexual partners and prostitution, suggesting the possibility of an increase in unsafe sexual behavior independent of prostitution or another factor.[15] In this study, crack use was strongly associated with multiple simultaneous STDs, which may be a reflection of multiple partner sexual behavior with greater opportunity for consequent exposure to multiple STDs, including GUD and HIV.

The association of GUD with HIV infection was more pronounced in women than men. This sex-specific association might be attributable to drug-related prostitution, likely a more prevalent behavior in women than men. If female addicts engage in sexual behavior in the context of crack use more frequently than male addicts, then events that depend on such high-risk sexual behavior, such as HIV infection and genital ulcer disease, will also be more common in women.

Polydrug abuse involving both crack cocaine and IV drugs is a potentially confounding variable that might account for the association of HIV infection and crack. Arguing against this proposition is the observation that the association of HIV infection with crack use increased when patients with recognized HIV risk factors (primarily IV drug users) were excluded from analysis. Furthermore, the association of HIV with GUD and multiple concurrent STDs also increased when patients with recognized risk factors for HIV were excluded from analysis. These observations are consistent with the hypothesis that high-risk sexual behavior may have accounted for HIV infection in these heterosexuals without recognized HIV risk factors.

Since voluntary HIV testing was employed in this study, it is possible that selection bias may have influenced these results, although the magnitude and direction of such bias is difficult to ascertain. It is possible that testing was encouraged more aggressively for patients with recognized risk factors for HIV, including those with multiple heterosexual partners and multiple episodes of STDs. On the other hand, many individuals who perceived themselves at high risk, particularly IVDUs, may have been less likely to consent to testing. The net effect of these biases may have been to underrepresent

IVDUs and overrepresent those with heterosexual risk factors who did not perceive themselves at risk. Despite this limitation, these data may provide important clues to the direction of the HIV epidemic in similar urban minority populations. In New York City, the estimated number of IVDUs has remained essentially stable over the last decade, while the estimated number of non-IV drug users, especially of crack cocaine, has continued to rise.[16] If these trends continue, sexual risk behavior associated with crack use may become the dominant mode of HIV transmission in this population.

Crack use history may also have been biased due to the previously reported association between crack use and GUD.[12] It is possible that a history of crack use was more consistently elicited and recorded in the clinic charts of patients presenting with genital ulcers than those with other STDs. This bias by itself would not account for the association seen with HIV and multiple concurrent STDs because in most cases these diagnoses were based on laboratory results that became available after the patient had left the clinic.

The frequent coexistence of HIV with GUD in this population is of concern for several reasons. Genital ulcers may enhance the efficiency of HIV transmission by several mechanisms. The isolation of HIV from the genital ulcers of HIV-infected individuals[17] raises the possibility that genital ulcers may increase the infectiousness of index partners by resulting in increased shedding of HIV. In addition, susceptibility of the contact who acquires GUD from the index partner may be increased. This might occur by disruption of the genital epithelium during ulcer formation as well as by recruitment of HIV-susceptible activated immune cells to the genital tract.[18,19] Thus, the high prevalence of both HIV and GUD in this population may create conditions similar to those in Africa where heterosexual transmission of HIV appears to be common.

The rising incidence of GUD in this population suggests that current efforts to promote reduction in risk behavior are insufficient. Such risk behavior reduction will play an essential role in controlling the parallel epidemics of GUD and HIV. The future of the HIV epidemic in this country may depend largely on the effectiveness of interventions aimed at similar urban minority populations where GUD and HIV infection are on the rise. Increased efforts should focus not only on STD control and risk behavior reduction, but also on prevention and treatment of non-IV drug use associated with sexual risk behavior. □

Reduction of High-Risk Sexual Behavior among Heterosexuals Undergoing HIV Antibody Testing: A Randomized Clinical Trial

Neil S. Wenger, MD, MPH, Lawrence S. Linn, PhD, Marsha Epstein, MD, MPH, and Martin F. Shapiro, MD, PhD*

ABSTRACT

Background. We evaluated the effect of HIV antibody testing on sexual behavior and communication with sexual partners about AIDS risk among heterosexual adults at a clinic for sexually transmitted diseases.

Methods. We randomized 186 subjects to receive either AIDS education alone (the control group) or AIDS education, an HIV antibody test, and the test results (the intervention group). These subjects were then followed up 8 weeks later.

Results. At follow-up, mean number of sexual partners decreased, but not differently between groups. However, compared with controls, HIV antibody test intervention subjects, all of whom tested negative, questioned their most recent sexual partner more about HIV antibody status ($P < 0.01$), worried more about getting AIDS ($P < 0.03$), and tended to use a condom more often with their last sexual partner ($P = 0.05$): 40% of intervention subjects vs 20% of controls used condoms, avoided genital intercourse, or knew their last partner had a negative HIV antibody test ($P < 0.005$).

Conclusion. HIV antibody testing combined with AIDS education increases concern about HIV and, at least in the short term, may promote safer sexual behaviors. Additional strategies will be necessary if behaviors risky for HIV transmission are to be further reduced. (*Am J Public Health.* 1991;81:1580–1585)

Introduction

Antibody testing for human immunodeficiency virus (HIV) has been proposed as part of the effort to control transmission of acquired immunodeficiency syndrome (AIDS).[1,2] Such testing is now routine for military personnel, federal prisoners, immigrants, and, in some states, those applying for marriage licenses.[3] Voluntary HIV antibody testing also is becoming more commonplace in special testing centers, medical practices, and clinics. The question of who should be tested has been debated by physicians,[4] ethicists,[5] activist groups, and presidential candidates,[6] but it remains controversial. Although HIV testing has become widespread, we are only beginning to understand its effects.[7]

Descriptive studies of high-risk individuals (homosexual men and intravenous [IV] drug users) requesting HIV testing and receiving positive test results have demonstrated some decrease in sexual activity among those tested.[8] However, almost no data have been published on the impact of testing on lower-risk populations, such as heterosexual adults sexually active with multiple partners, the overwhelming majority of whom will have negative test results. Yet such information is essential in developing public policy. A negative result on an HIV antibody test could be used either to justify resumption of a high level of sexual activity or to stimulate more cautious behavior.

No randomized trials of HIV testing have been reported to date. Thus, to evaluate the impact of HIV antibody testing on sexually active heterosexual adults, we conducted a randomized trial in a Los Angeles clinic for sexually transmitted disease (STD).

Methods

Consecutive individuals attending an urban STD clinic between January and March 1988 were approached to participate in a randomized trial of HIV antibody testing. The clinic did not offer HIV antibody testing at the time of this study.

Of 724 consecutive patients, 224 were judged ineligible according to preset criteria: they had been previously approached about study participation (21%) or they were younger than 18 years of age (14%), unable to speak English (46%), of homosexual or bisexual orientation (4%), unavailable due to constraints of the clinic (i.e., sequestered by peace officers or primarily participating in other clinic areas [10%]), unable to give informed consent (4%), or unable to give a follow-up address (1%). Of the 500 eligible patients, 259 (52%) were interested in receiving free, confidential HIV antibody testing and 256 (51%) were willing to participate in the randomized trial. Those attending the clinic, those eligible for the study, and those participating were similar in gender and age; there were more Blacks in the study sample than among clinic attendees (84% vs 72%) due to the exclusion of non-English speakers (all of whom were Hispanic).

This paper was submitted to the journal December 4, 1990, and accepted with revisions July 1, 1991.

Upon entering the clinic, patients were informed of the possibility of receiving free, confidential HIV antibody tests along with the routine clinic blood draw for syphilis serology. The nature of the randomized trial was explained to eligible patients who wished to receive the HIV antibody test. Signed consent was obtained for the study and for HIV antibody testing.

Subjects then completed a self-administered questionnaire that included items to elicit (1) demographic information; (2) knowledge about AIDS (six true/false questions); (3) mental health (a five-item global mood inventory);[9] (4) worry about general health (a four-item "health/worry" index);[10] and (5) information about their last sexual partner, including length of relationship, perceived sexual experience, and chance of carrying HIV. Communication with sexual partners was evaluated by inquiring as to whether subjects had *asked* either partner in the past month or their most recent partner (1) whether that partner had been tested for antibody to HIV and, if so, what the result was; (2) whether that partner had used IV drugs; and (3) how many previous sexual partners that partner had. Subjects' sexual behavior was measured as (1) the number of sexual partners in the past month, (2) the number of episodes of vaginal and anal intercourse and of oral sex with and without a condom in the past month with all sexual partners, and (3) the number of sexual acts with their most recent partner.

After completing the questionnaire, all subjects participated in an educational module in which they (1) received a written pamphlet that explicitly discussed safer and unsafe sexual acts and explained condom use;[11] (2) watched a 15-minute videotape that discussed behavior risky for contracting AIDS and promoted condom use and discussion of risk with sex partners;[12] and (3) participated in a 10-minute, one-on-one counseling session with a physician blinded to randomization status. The counseling focused on assessing personal risk, discussing the elements of the HIV test, and answering any questions about AIDS or HIV testing. All aspects of usual HIV pretest and posttest counseling were covered with every subject.

After completing the educational module, subjects were called for the usual clinic blood draw by the clinic nurse, who opened the sealed randomization envelope. Subjects randomized to HIV testing (the intervention group) were informed of that fact and had an extra tube of blood drawn. Subjects randomized not to receive the test (the control group) were offered a list of locations for free, anonymous HIV antibody testing.

Serum samples underwent enzyme-linked immunosorbent assay (ELISA) for HIV. Repeat positive results on ELISA tests were submitted for confirmatory western blot analyses. Negative test results were revealed to subjects, in person or by telephone, approximately 2 weeks after study entry and were accompanied by the same risk reduction message that all intervention and control subjects received during the pretest counseling. Subjects testing positive received face-to-face, in-depth counseling with analysis of risk factors. Long-term medical and psychological follow-up was arranged.

Follow-up questionnaires were mailed to all subjects 8 weeks after study entry. In addition to the names, addresses, and telephone numbers they had provided, subjects were traced by using public health and social service resources, canvassing nearby hospitals and penal institutions, and monitoring the clinic. In addition to the questions on the first questionnaire, subjects were asked whether they were worried about getting AIDS, whether they had been HIV tested, and what their responses were to testing. If the questionnaire was not returned after repeat mailings and telephone calls, a trained research assistant administered it over the telephone. The number of responses obtained by telephone did not differ between the two groups.

Of the 256 individuals consenting to participate, 125 were randomized to the intervention group and 131 to the control group. Every effort was made to follow up each subject. However, follow-up efforts revealed that 22 intervention subjects (18%) and 23 control subjects (18%) had provided untruthful names, addresses, and telephone numbers when they entered into the study—before randomization. These subjects were thus excluded from the study. The excluded subjects in the two groups were similar with regard to demographic characteristics, communication with partners about AIDS, and sexual behavior (Table 1).

Of the 103 remaining intervention subjects, 11 (11%) could not be followed up (1 left the clinic before blood could be drawn, 2 could not be reached to receive test results, 1 refused to be informed of his [positive] result, and 7 could not be located or refused to complete follow-up questionnaires). Similarly, of the remaining 108 control subjects, 14 (13%) did not complete follow-up questionnaires. Those subjects not followed up were similar at baseline between the two groups except for small differences in age and knowledge about AIDS. Compared with those who were followed up, they were somewhat less likely to be Black (Table 1). Overall, the 70 subjects who were not followed up in this trial did not differ significantly from those who were followed up in terms of demographics (except race), knowledge about AIDS, number of sexual partners last month, or previous episodes of STD. The remaining 92 subjects in the intervention group and 94 subjects in the control group make up the longitudinal sample for this study.

Three of the 124 subjects receiving an HIV antibody test through this study tested positive for HIV on ELISA. All were confirmed on western blot analysis. At follow-up counseling, one revealed that he had denied his homosexual contact to enter the study. The second was a woman with two children and an IV drug–using ex-husband; she received follow-up care but refused to complete the follow-up questionnaire. The third was a male who declined to receive his test result, fearing that he might become depressed if he were positive; he also declined to complete the follow-up questionnaire. Thus, all subjects who were followed up in the intervention group received a negative HIV antibody test result approximately 6 weeks prior to completing the follow-up questionnaire. Among the 94 control group subjects completing the follow-up survey, 10 (11%) obtained HIV antibody tests elsewhere. (Nine reported a negative result and one never obtained the result.)

Analyses were performed only on prespecified hypotheses using an intention-to-treat protocol in which subjects were analyzed in their original randomized groups, regardless of whether persons in the control group obtained the HIV test from an outside source. Baseline differences between intervention and control groups for continuous variables were assessed with t tests or Wilcoxon tests, depending on the variable's underlying distribution; differences for dichotomous variables were assessed with chi-square tests. Repeated measures analysis of variance for continuous variables (using SAS Proc GLM) and log-linear models for dichotomous variables (using SAS Proc CATMOD) were used to evaluate the effects of group differences, changes over time, and interactions.

*$\chi^2 = 4.7$, $P = 0.03$ for difference between groups.

Results

The characteristics of subjects completing the study are shown in Table 2. The mean age was 27 years. Most were male, Black, and high school graduates and were unmarried, employed, and reported an income of less than $1000 per month; 6% reported knowing someone with AIDS, 5% used IV drugs, and 7% had been previously tested for antibody to HIV. Only race differed significantly between the groups ($P = 0.03$). Baseline scores for knowledge about AIDS, mental health, and health/worry were similar.

At baseline, subjects reported a mean of 1.8 sexual partners in the past month compared with 2.9 for the same month the previous year ($P < 0.001$). They reported a median of 14 lifetime sexual partners, age at first sexual intercourse of 15, and a mean of 2.7 previous episodes of STD. The groups did not differ in these baseline values or in the proportion engaging in various sexual acts with all partners over the past month (Table 2).

The two groups did not differ in length of sexual relationship with the last partner, in estimated number of previous sexual partners that this last partner had had, or in estimates of this partner's chance of carrying HIV. Nearly half reported having asked if their last partner had used injected drugs, 14% had asked if that partner had been tested for HIV, and 26% had asked how many previous sexual partners this partner had had. There were no significant differences between groups at study entry in these measures of communication either with the last partner or with all partners in the past month. Re-

garding their last sexual encounter, 88% reported vaginal intercourse without condoms (12% with condoms) and 9% reported anal intercourse without condoms (1% with condoms). The groups did not differ in baseline measures of sexual activity (Table 3).

At follow-up, there were no differences between intervention and control groups or from baseline in measures of AIDS knowledge, mental health, or health/worry (Table 4). However, when specifically asked at follow-up if they were concerned about AIDS, intervention subjects expressed greater concern than controls ($P < 0.03$). Comparing those who were more worried with those who were not, intervention group subjects were significantly more likely to be *more* worried about getting AIDS than they had been 1 month previously (45% vs 26%, $P = <0.01$).

Intervention subjects were more likely than control subjects to report at follow-up that they had asked their last sexual partner about their risk of carrying HIV (Table 5). Inquiries about that partner's HIV status rose from 13% to 41% in the intervention group, significantly more than the 15% to 24% rise in the control group ($P < 0.01$, difference = 18%, 95% confidence interval [CI]: 7.4%, 29%). This difference was due to two effects: 29% of intervention subjects *had not* asked about HIV status at baseline but did so at follow-up, compared with 17% in the control group ($P = .01$), and only 1% of intervention subjects who *had* asked about HIV status at baseline "backslid" and failed to do so at follow-up, compared with 9% of control subjects ($P = .01$).

The proportion of subjects who reported having asked their most recent sexual partner about that person's number of prior sexual partners increased in both groups: from 23% to 57% in the intervention group and from 29% to 53% in the control group. Fifty percent of intervention subjects asked about IV drug use at follow-up compared with 34% of control subjects; however, differences between groups were not significant (Table 5).

Overall, 51% of intervention subjects and 32% of control subjects asked their last sexual partner more questions at follow-up than at baseline about their risk of carrying HIV (difference = 19%, 95% CI: 5%, 33%).

As might be expected after a visit to an STD clinic, the last sexual partner was a first-time partner for only 14% of subjects at follow-up (vs 24% at baseline, $P < 0.05$). There were no differences at follow-up between groups in the percentage for whom the most recent sex partner was a new partner, in the length of sexual relationship with that sexual partner, in the subject's perception of that partner's prior sexual experience, or in the subject's perception of that partner's risk of carrying HIV.

Subjects in both groups decreased their total number of sexual partners per month from 1.9 and 1.7 partners in the intervention and control groups, respectively, at study entry to 1.4 and 1.3 partners, respectively, at follow-up ($P < 0.01$), though the groups did not differ (Table 5).

Although the decline in the number of partners with whom the subjects had vaginal, oral, or anal sex was similar between the two groups, 27% of intervention subjects avoided vaginal or anal intercourse *without a condom* with their most recent sexual partner compared with 13% of control subjects. This approached statistical significance ($P = 0.05$) for a difference between groups. Analyzed separately, the

****$P < 0.003$ for group differences in change over time.

intervention group avoided intercourse without a condom more at follow-up than at baseline ($P < 0.0001$), whereas the control group did not ($P = 0.34$). Three subjects in the intervention group and none in the control group reported having only oral sex; all other subjects in both groups used condoms for vaginal or anal intercourse (Table 5).

The difference between the groups in the rate of "protected" sexual activity was greater when knowledge of a partner's risk factors was taken into account. Among those having vaginal or anal intercourse without condoms with their last partner, 13 intervention subjects (14%) and 6 control subjects (6%) had asked about this partner's HIV serostatus and had been told the partner was seronegative. Thus, at follow-up, fully 40% (37 of 92) of intervention subjects used a condom, had only oral sex, or stated that they knew their partner's HIV serostatus was negative, whereas only 20% (19 of 94) of control subjects did so ($P < 0.003$, difference = 20%, 95% CI: 7.1%, 33%).

Discussion

Nonrandomized interventions that are intended to change sexual behavior are difficult to evaluate because of the underlying trend toward decreasing rates of activities at risk for transmission of HIV. In this study, all subjects received AIDS education and the components of pre- and posttest counseling, and all were randomized to receive or not receive an HIV antibody test. Compared with individuals in the control group, intervention subjects worried more about getting AIDS (even though they received *negative* HIV test results) and were more likely to have asked partners about AIDS risk factors. HIV testing also was associated with a decrease in unprotected vaginal and anal intercourse. The intervention did not affect our measures of knowledge about AIDS, health/worry, or mental health status.

The behaviors protective for HIV seen among the intervention group in this study are consistent with findings in some observational studies of homosexual men. For example, in an observational study of homosexual men apprised of negative HIV antibody status,[13] van Griensven and colleagues found fewer sexual partners, more communication with partners about HIV serostatus, and increased condom use. Coates et al. found that homosexual men who reported a negative HIV status were more likely to reduce unprotected anal intercourse than those choosing not to be tested.[14,15] Three other observational studies, however, found no substantive behavioral change associated with knowledge of a negative test result in homosexual men.[16–18]

The findings in the current study of greater worry about AIDS and decreased risky sexual behavior among individuals testing negative for HIV are particularly important in light of speculation that a negative test result would adversely affect perceived risk of HIV infection and would be viewed as license to continue "business as usual."[19,20]

While condom use is generally regarded as protective against HIV transmission, some contend that communication with partners about their risk of carrying HIV often is not very useful[21] and might be deleterious if a partner lies.[22] On the other hand, Hearst and Hulley suggest that the sexual partner's probability of HIV infection is "by far the most important" predictor of infection risk; they state that "the best advice we can give our patients is to choose their partners carefully."[23] In this study, intervention subjects increased questioning of partners about HIV testing significantly more than controls did. As with changes in condom use, this may reflect heightened concern about becoming infected with HIV. However, it also may be a result of having been tested; perhaps individuals who know their personal test result are more willing to ask about HIV serostatus.

There is a danger that individuals at STD clinics might fail to understand the "window period" before seroconversion and be incorrectly reassured of negative serostatus in pursuing future unprotected sexual behavior. Although intervention subjects were more likely to use condoms, the majority still had unprotected vaginal or anal intercourse with their last partner. Educational efforts need to stress the meaning of a negative HIV test result, especially during this period after an STD.

The findings of this study need to be interpreted with caution. While intervention subjects significantly decreased risky behavior compared with controls, a large proportion continued to engage in activities at risk for transmission of HIV. The sexual behavior reported in this study is self-reported; subjects may have been untruthful, but it is doubtful that the propensity to lie differed between groups. In addition, 27% of the original sample could not be followed up. Finally, multiple comparisons were performed; however, each was a preplanned analysis, and the fact that 4 of 10 were associated with P values

of .05 or less, all in a similar direction, is more than would have been expected by chance alone.

Furthermore, this study was conducted among a predominantly Black, unmarried, low socioeconomic status population attending an STD clinic. Although this group is of considerable importance because their behaviors may promote the spread of HIV infection among the general heterosexual population,[24–26] findings may not be generalizable to other heterosexuals at lower risk of HIV infection. Half the clinic population was unwilling to receive an HIV test. Indeed, this study compares only the 26% of the STD clinic population that met inclusion criteria, were willing to receive an HIV test and participate in a clinical trial, and were followed up. Results of the trial may apply only to this select group. Lastly, the follow-up period for this study was short. Behavior alterations found at 2 months of follow-up may not have persisted.

This study was carried out as a research project offering free, confidential HIV testing. The fact that subjects accepted testing under such circumstances does not predict the acceptance of testing under other conditions.[27] Perhaps the benefits of testing would be diminished if strict confidentiality could not be assured.[28] Discrimination resulting from reporting of positive HIV test results may produce negative effects not seen in this trial.[29] Confidentiality, sensitivity, and efforts to reduce the stigma of positive HIV test results must be part of effective testing programs.

The findings of this study provide assurance that HIV testing in at-risk heterosexuals is safe: subjects, all of whom tested negative for HIV, did not increase risky sexual behavior and did not suffer adverse psychological consequences of testing. The findings also suggest that, for this heterosexual population, HIV antibody testing is effective in reducing certain risky sexual behaviors, perhaps through the mechanism of increasing the level of worry about acquiring HIV infection. Further studies of testing are needed to assess its long-term effects and to examine its effects in other heterosexual populations with different risk profiles. Finally, although one-time interventions such as that described here may reduce at-risk activities, they do not eliminate them. Additional interventions may well be required to reduce further the risk of HIV transmission. □

Behavior Changes after Notification of HIV Infection

ABSTRACT

Background. To learn more about how people who did not volunteer for testing react to information about HIV infection, we assessed short-term behavior changes in HIV-positive blood donors.

Methods. Blood donors who were notified at the New York Blood Center that they were HIV positive were asked to participate in a study. A nurse elicited a medical history, performed a limited medical examination, and asked participants to complete a questionnaire that included questions about drug use, sexual behavior, and psychological characteristics. Participants were asked to return in 2 weeks to complete another questionnaire.

Results. Many fewer men and women reported engaging in unsafe sexual behaviors in the 2 weeks preceding the follow-up visit than had reported such behaviors prior to notification. These changes were greater than those other investigators have reported, but about 40% of the participants still reported unsafe sexual activity at the follow-up interview.

Conclusions. To make nonvolunteer screening programs for HIV infection more effective in reducing the spread of HIV infection, we need to learn more about how to help people change their high-risk behaviors. (*Am J Public Health.* 1991;81:1586–1590)

Introduction

The main goal of blood center screening programs for human immunodeficiency virus (HIV) is to ensure the safety of the blood supply. Another important goal should be to provide information and support to HIV-positive donors to help them reduce the probability that they will infect others.[1,2] The data are inconclusive as to whether screening and notification programs result in positive behavior changes.[3,4] Several researchers have found that HIV-positive individuals showed greater reductions in risk than those who tested negative or who had not been tested,[3,5] but others have found no changes or changes only in certain behaviors.[6–9]

Almost all published reports of the impact of HIV testing and counseling programs are based on data from self-identified homosexual or bisexual men who volunteered for testing. Since many current and proposed screening programs involve people with different risk factors who did not volunteer for testing, it is critical to understand more about how such persons react to information about HIV infection. In this paper, we describe short-term behavior changes in blood donors who were notified that they were HIV-antibody–positive.

Methods

Screening and Notification

Since 1983, the New York Blood Center (NYBC) has asked all donors to indicate on a confidential form whether their blood should be used for transfusions or for studies only.[10] Donors are told to indicate that their blood should be used only for research ("studies only") if they have a risk factor for HIV infection. The NYBC removes all such blood from distribution, regardless of antibody screening results.

Since April 1985, the NYBC has supplemented the confidential self-exclusion program by screening all blood donations for HIV antibodies with enzyme-linked immunosorbent assays (ELISAs). Any sample with two positive ELISA tests and a confirmatory Western blot assay is considered "confirmed positive."

All HIV-positive persons who donated blood between June 1, 1986, and February 28, 1988, and who came to the Center after notification were asked to participate in this study.[1] A letter was mailed to all confirmed HIV-positive donors, asking them to come to the NYBC to discuss a "finding of importance to your health." If two attempts to contact a donor failed, a certified letter was sent explaining the test results and encouraging the donor to come to the Center or to contact a physician for counseling.

A nurse clinician with psychiatric training saw each seropositive donor who

came to the Center and explained the meaning of the test results, the potential impact of infection on the donor's health, and ways to prevent the spread of the virus to others. Donors were also given written materials about HIV. The nurses gave the donors counseling and emotional support, answered questions, and assessed the donors' ability to cope with the information.

Sociodemographic and Medical Information

For all blood donors, the NYBC records age, gender, date of donation, and whether the donor used the confidential self-exclusion option. For each study participant, the nurse elicited a complete medical history, including information about possible HIV risk factors, and performed a limited medical examination. A tube of blood was drawn for use in a verification Western blot test and other blood tests. At the end of the first visit, the nurse recorded information about any HIV risk factors that the donor reported.

Questionnaire

After the medical exam and interview, the nurse asked each study participant to complete a questionnaire, in private, that asked about their use of intravenous drugs and whether they had engaged in numerous specific sexual activities, including vaginal sex and various types of anal and oral sex, in the previous 2 weeks. The questionnaire also asked men whether they used a condom always, almost always, sometimes, rarely, or never. Using the same categories, it asked women how frequently a partner used a condom with them. The baseline questionnaire asked participants how many sexual partners of the same sex and how many of the opposite sex they had had in the past month and in the past year, and whether they thought of themselves as exclusively heterosexual (straight), predominately heterosexual, equally homosexual and heterosexual (bisexual), predominately homosexual, or exclusively homosexual (gay).

The questionnaire also included questions about psychological characteristics, such as self-esteem, perceived locus of control, and optimism; sexual and social functioning; social support; coping strategies; health concerns; and depressive symptoms.[11] At the follow-up visit, participants were asked to complete another questionnaire, which contained questions about sexual behavior in the preceding 2 weeks.

Analyses

If information from the structured interview, questionnaire, or nurse clinician summary indicated the presence of a risk factor, we assumed that risk factor to be present. For example, if a male donor reported on the questionnaire that he had had male sexual partners in the previous year, he was classified as having male sexual contact as a risk factor, even if he reported contradictory information during the interview.

We considered participants to have engaged in unsafe sex if they reported that they had engaged in vaginal or anal intercourse and had not always used a condom, that they had engaged in oral sex without a condom, or that they had been a recipient or giver of oral-anal sex.

We compared subgroups of seropositive donors using chi-square statistics for categorical variables and *t* tests for continuous variables. We estimated the associations between donor characteristics and sexual behavior at the 2-week follow-up visit with Pearson product-moment correlations for continuous variables, and point-biserial correlations or fourfold point correlations for dichotomous variables.[12] To estimate the independent effect of donor characteristics on subsequent behavior, we estimated a logistic regression model. We used a forward stepwise selection procedure to select variables that were statistically significant predictors ($P < .05$).

Results

Nonparticipants

During the study period, there were 708 confirmed HIV-antibody–positive donors at the NYBC. Letters to 79 donors (11%) were undeliverable or unclaimed. Another 90 donors (13%) did not respond to the letters from the Blood Center and were notified of their test results by certified mail. Of the 539 donors who contacted the Blood Center, 5 were informed of their results by telephone; 140 agreed to come to the site regularly only to have results of blood tests monitored; 1 was enrolled in another research protocol; 2 were autologous transfusions and were excluded. Two hundred seventy-one patients enrolled in the study, representing 50% of the donors who contacted the study team and 38% of detected seropositive donors. Two hundred and sixty-one of the participants completed an initial interview and 243 completed a baseline questionnaire. Eight study participants completed neither a questionnaire nor a medical interview at the initial visit.

Participating donors were somewhat more likely than nonparticipants to be female (22% vs 18%) and to have said that their blood should be used for studies only (75% vs 69%), but these differences were not statistically significant. The average ages of the two groups were almost identical.

One hundred ninety-six study participants (72%) returned for the 2-week follow-up visit. The median follow-up time was 16 days (mean = 23 days). Those who did not return for the follow-up visit were not significantly different from those who did with respect to CD4 count, age, gender, ethnicity, education, marital status, risk factors, self-exclusion status, period of donation, any of the psychological characteristics measured, or most of the coping strategies measured. However, those who did not return were more likely to be cautious about potential casual routes of transmission (e.g., letting others use towels or silverware that he or she had used) ($P < .05$), less likely to talk with friends to cope with their fears and worries ($P < .01$), and less likely to make themselves feel better by letting out anger ($P < .05$).

Sociodemographic Characteristics

The study population was predominately male, single, young, white, and highly educated, reflecting the characteristics of blood donors in general, although it was very heterogeneous (Table 1).

Risk Factors

The risk factors identified for both men (Table 2) and women (Table 3) are similar to those for the general population of HIV-infected persons. The most commonly reported risk factor for men was sexual contact with another man. Sexual contact with IV drug users and use of intravenous drugs were also reported frequently. A surprising finding was that many men and women who donated for transfusion apparently were not aware of the risk factors for infection.

Reported Behavior Prior to Notification

Most men (63.1%) reported having had a male sexual partner in the previous year, but more than a third had not; 40% reported having had a male sexual partner in the previous month (Table 4). More than 40% of the men reported having had one or more female sexual partners in the

None of above risk factors identified during initial contact	32.7%	1

previous year, and almost a quarter of them reported having had a female sexual partner in the previous month.

Women were much more likely than men to report having had a sexual contact with the opposite sex in the previous year (66.7%), and the vast majority (78.7%) reported no sexual contact with another woman in the previous year. About 40% of both men and women reported that they always used condoms with their sexual partners.

More than 80% of both men and women reported that they had been sexually active in the week prior to notification and more than half had engaged in unsafe sexual practices (Table 5). The rates of sexual activity were comparable for men and women, although men were more likely to have engaged in unsafe sex. Fifty-four men and 9 women who reported that they had had no sex partners in the past month reported that they had engaged in specific sexual activities with others. This discrepancy may have been due to the fact that the questions about partners asked "How many *different* partners of the same (opposite) sex have you had?" (italics added). Some respondents may have answered zero if they had had only a single partner.

Reported behaviors also were not always consistent with self-identified risk factors. Thirty-four percent of the men who said that they thought ofthemselves as exclusively heterosexual reported having had sex with another man.

Behavior Reported at the Follow-Up Visit

At the follow-up interview, almost two thirds of both men and women reported having been sexually active in the previous week, and more than one third of both men and women reported engaging in unsafe sex. To test for the possibility that there had been differences in the frequency of unsafe behavior in different time periods, we compared the proportion of subjects who reported unsafe behaviors in three approximately equal periods of the study and found no consistent differences.

The strongest correlate (not presented here) of whether respondents had engaged in unsafe sex in the period between the two interviews was whether they had engaged in unsafe sex in the week prior to the initial (notification) interview. Only 15.4% of the respondents who reported having had no unsafe sex in the week prior to notification reported having unsafe sex in the period preceding the follow-up interview, but 54% of those who reported having had unsafe sex in the week prior to the initial interview also reported having had unsafe sex before the follow-up interview. Persons who reported that they had had unsafe sex in the period before the follow-up interview also tended to be younger, said at the time of donation that their blood should be used for studies only, reported having had more sexual partners than others at the initial interview, were less concerned about casual transmission, and were less likely to report engaging in a range of health-promoting activities.

In a logistic regression model (Table 6), the independent significant predictors of unsafe sex were having said their blood should be used for studies only, having more partners than other participants in the month preceding the initial interview, and participating in unsafe sex before the initial interview.

Discussion

To our knowledge, this is the first study that has evaluated behavior changes in a heterogeneous group of persons who

had not volunteered for HIV screening. Although every donor should have been notified that their blood would be tested for HIV antibodies, very few donated blood for the explicit purpose of being tested and many were unaware that the testing was done.[13] The results reported here provide insights into the types of reactions that other screened populations, such as immigrants[14] and hospitalized patients,[2] may experience.

A surprisingly high number of participants did not report being subject to a major HIV risk factor. We do not think this implies an unrecognized mode of transmission. Rather, we think many individuals do not recognize or acknowledge their risky behaviors. Many public health messages may not be optimally effective because they emphasize high-risk groups instead of high-risk behaviors. Our finding that many men who described themselves as exclusively heterosexual also reported having had sex with another man emphasizes that many individuals who engage in risky behaviors do not identify themselves with the associated high-risk groups. It may also be true that many individuals deny their personal risk even though they are aware of behaviors that increase the risk of HIV infection.[15] Much more needs to be known about the factors related to self-awareness of HIV risk.

The reductions in risky behaviors reported here are greater than those reported by some other investigators.[6,8;cf. 3,7] This may be due to the counseling that was provided, the self-selecting nature of those who enrolled in the study, or both.[8] It may also be true that sexual activity decreases after seroconversion because infection is most likely to occur during a peak of sexual activity.[16] We had no way of verifying reports of behavior, and participants may have underreported their risky behaviors at the follow-up interview.

Even if the reported reductions in risky behaviors were true and were due to the counseling provided, it is disconcerting that about 40% of the participants still reported having engaged in unsafe activities at the follow-up interview. This persistence in unsafe behavior by individuals who were given personal counseling and were motivated to join a psychosocial research project emphasizes the difficulty of encouraging people to adopt safer sexual behaviors. Whether long-term programs would be more successful at changing behavior remains to be determined.

Of the many psychosocial characteristics studied, only previous sexual behavior and use of the confidential self-exclusion option predicted the continuance of unsafe sexual behavior at the time of the follow-up interview; persons who engaged in high-risk behaviors and were aware of their risk were less likely to change their behavior. This finding is similar to that of McCusker and colleagues,[6] who found that previous sexual practices were the strongest predictors of subsequent practices. A major focus of our study was to learn more about the psychological and social characteristics that are related to beneficial behavior changes and to identify individuals who would benefit most from psychosocial support programs. Our lack of findings in these areas is discouraging. We examined only short-term behavior changes, and the effects of

these characteristics may be less evident on short-term than on long-term behavior changes. There have been several excellent studies of the psychological and social factors related to behaviors that increase the risk of HIV infection,[6,8,17–20] but we still need to know much more about such factors. We currently are analyzing the relationship between various individual characteristics and behavior changes over longer periods of time.

Only about 38% of detected seropositive donors enrolled in the study, and only 28% completed both waves of data collection. We think it is likely that those who participated in this study were the most concerned about their health and were the most prone to change their behavior. Such self-selection, which will be almost inevitable in any HIV screening and counseling program, makes it extremely difficult to promote safe behavior after HIV screening.

Several researchers have argued that we should exercise extreme caution when developing routine screening programs.[2,6,8,14,21] The data reported here emphasize the difficulty of promoting voluntary behavior changes in seropositive individuals. The short-term persistence of unsafe behavior in this sample emphasizes the need for long-term follow-up.[22] We are currently evaluating a randomized controlled trial of such a program with blood donors.[1,23] Unless we learn more about ways to maximize the effectiveness of screening programs in promoting the desired behavior changes, they are likely to be a costly but ineffective and inefficient method of slowing the spread of HIV infection. □

Acknowledgments

This research was supported by grants from the National Heart, Lung, and Blood Institute (HL 35403-0151) and American Foundation for AIDS Research (AmFAR). The authors acknowledge and express their appreciation for the work of the other nurse clinicians who provided support and counseling to the donors and made the research reported in this paper possible. They include Catherine Tendler and Nalda Brodegaard. The authors thank Mary Hendricks, William McMullen, and Cathy Simon for help with data management and analyses and Carol Gerrior for help with manuscript preparation. The authors and staff of the project express their greatest respect for and appreciation to the seropositive individuals who contributed their time and thoughts to this project.

Knowledge about AIDS and HIV in the US Adult Population: Influence of the Local Incidence of AIDS

Linda F. McCaig, MPH, Ann M. Hardy, DrPH, and Deborah M. Winn, PhD

ABSTRACT

Background. Accurate information about acquired immunodeficiency syndrome (AIDS) and human immunodeficiency virus (HIV) is important for prevention. This study determined whether AIDS knowledge varied among populations residing in areas with a low, medium, or high incidence of AIDS.

Methods. Respondents to the 1988 National Health Interview Survey of AIDS Knowledge and Attitudes, which is based on a nationally representative sample of 29 659 adults, were rated on their knowledge about modes of HIV transmission, general knowledge about AIDS, and misperceptions about HIV transmission through casual contact.

Results. Persons 50 years of age or older, Blacks, Hispanics, and persons with less than a high school education had lower knowledge scores and higher misperception scores. Residents of the high-incidence area had more misperceptions than those who lived in the medium- or low-incidence areas. Sociodemographic determinants of scores were important factors overall and within each AIDS incidence area.

Conclusions. These data suggest that the ability of educational messages to reach and be absorbed by individuals nationwide is less dependent on whether they live in an area with a high incidence of AIDS and more dependent on other demographic variables. New and continued efforts are needed to improve knowledge in older persons, minorities, and the less educated in all parts of the country. (*Am J Public Health.* 1991;81:1591–1595)

Introduction

On the national and local levels, much effort in the control and prevention of human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS) has focused on educating both the general public and specific high-risk groups. It is important to evaluate these efforts periodically to determine if educational messages have reached their targets and to examine factors that influence knowledge levels. Evaluation of the national AIDS public information campaign has involved a variety of methods and data sources, including the National Health Interview Survey (NHIS) current health topic on AIDS Knowledge and Attitudes.

AIDS incidence rates in a geographic area may affect the public's knowledge about AIDS and HIV infection for several reasons. For one thing, demographic variables (e.g., education) that are associated with different levels of knowledge may be distributed differently among low-, medium-, and high-incidence areas. For another, local educational efforts may have begun earlier or been more intense in areas of higher incidence. Moreover, persons in high-incidence areas may have a greater chance of knowing someone with AIDS and/or may perceive themselves to be at greater personal risk of developing AIDS, either of which factor may increase their opportunity and desire to learn more about the disease. Finally, national polls have found that, as the distance from the major AIDS epicenters increases, the public perceives AIDS to be less threatening.[1] Thus, if knowledge of AIDS and HIV infection is affected by the incidence of AIDS in the area under study, this information should be incorporated into the planning of public information efforts.

This study examined data from the 1988 NHIS AIDS Knowledge and Attitudes survey to determine how knowledge varied by demographic characteristics and among populations residing in areas with low, medium, and high annual incidence rates of AIDS. Because the NHIS is the only survey of AIDS knowledge that is based on a national probability sample, it provided a unique opportunity to evaluate knowledge of AIDS and HIV infection by incidence areas on a national level.

Methods

The NHIS, a cross-sectional sample survey of the US civilian, noninstitutionalized population, has been conducted annually since 1957 by the National Center for Health Statistics, one of the Centers for Disease Control (CDC).[2] Each year, members of 50 000 households across the country are interviewed in person by US Bureau of the Census personnel. The NHIS sample design is a multistage, stratified, probability sample of the US population.[3]

The first questionnaire about AIDS was included in the NHIS in 1987. The questionnaire was then revised, and data collection with the version of the AIDS survey described in this report began in 1988. The questionnaire, administered to one randomly selected adult aged 18 years

At the time of the study the authors were with the Division of Health Interview Statistics, National Center for Health Statistics, in Hyattsville, Md.

This paper was submitted to the journal October 10, 1990, and accepted with revisions May 6, 1991.

TABLE 1—Questions and Answers on Which the Transmission Knowledge, General Knowledge, and Misperception Scores Were Based

Question	Correct Answer[a]
Transmission Knowledge Scores	
ANY person with the AIDS virus can pass it on to someone else through sexual intercourse.	DT or PT
A pregnant woman who has the AIDS virus can give the AIDS virus to her baby.	DT or PT
How likely do you think it is that a person will get AIDS or the AIDS virus infection from sharing needles for drug use with someone who had the AIDS virus?	Very likely or somewhat likely
General Knowledge Scores	
AIDS is especially common in older people.	DF
AIDS usually leads to heart disease.	DF
AIDS leads to death.	DT
A person can be infected with the AIDS virus and not have the disease AIDS.	DT
ANY person with the AIDS virus can pass it on to someone else through sexual intercourse.	DT or PT
There is a vaccine available to the public that protects a person from getting the AIDS virus.	DF
There is no cure for AIDS at present.	DT
Misperception Scores[b]	
How likely do you think it is that a person will get AIDS or the AIDS virus from—	
living near a home or hospital for AIDS patients?	
working near someone with the AIDS virus?	
sharing plates, forks, or glasses with someone who has the AIDS virus?	
using public toilets?	
being coughed on or sneezed on by someone who has the AIDS virus?	
attending school with a child who has the AIDS virus?	
mosquitoes or other insects?	

[a]DT or PT = Definitely true or probably true; DF = Definitely false.
[b]The correct answer to all of the misperception questions is "Definitely not possible or very unlikely."

or older in each family included in the NHIS sample, was designed primarily to estimate adults' knowledge about AIDS, HIV transmission, and prevention of HIV infection. In the questionnaire, the term "AIDS virus" was used instead of "HIV" because it was believed to be more readily understood. In this report, however, "AIDS" refers to the disease, "HIV" to the virus.

Sample persons were classified by the annual incidence rate of AIDS in their county of residence. The annual incidence rates of AIDS in census-defined metropolitan statistical areas (MSAs) with 500 000 or more population for the period April 1988 to March 1989 was ascertained from the *HIV/AIDS Surveillance Report* published by CDC.[4] The 94 MSAs listed in the CDC report were then compared with the counties included in the NHIS sample.[5] The 6 MSAs not part of the NHIS sample were excluded, and the remaining 88 MSAs were ranked according to incidence rate from lowest to highest. Three groups were then determined by two break points in the list where the rates in one area differed from those in the next higher area by 1.5% or more. Also considered in making these determinations was that each incidence area would have a sufficient sample size for analyses. The incidence areas were classified as low (fewer than 10 cases per 100 000 population, 46 MSAs, range 1.9–9.6), medium (10 to 27 cases per 100 000 population, 35 MSAs, range 11.1–26.6), or high (more than 27 cases per 100 000 population, 7 MSAs, range 34.7–99.7).

Incidence rather than prevalence rates were used to classify counties because that was the measure available as reported by CDC. However, in 1988, ranking cities by prevalence or incidence rates would probably have yielded the same order. CDC provides annual AIDS incidence data only for MSAs with 500 000 or more population to ensure the anonymity of persons with AIDS who reside in small cities or rural areas.[4] Forty-one percent of the NHIS sample did not live in the MSAs listed in the CDC report; therefore, it was not possible to classify all counties in the NHIS sample as to their incidence of AIDS.

In 1988, 29 659 adults—or about 90% of eligible sample persons—responded to the AIDS questionnaire; of those, 17 277 persons could be classified into an AIDS incidence area. This includes 58% of the NHIS sample eligible for the AIDS Knowledge and Attitudes survey and represented 59% of the US population aged 18 years and over. For results presented by AIDS incidence area, only the part of the sample with incidence assigned was used; for national estimates, the entire NHIS sample eligible for the AIDS Knowledge and Attitudes survey was used.

Three scales reflecting AIDS knowledge were constructed: transmission knowledge, general knowledge, and misperception scores. The 1988 NHIS AIDS questionnaire contained three questions that were used in this report to assess knowledge about recognized modes of HIV transmission (i.e., sexual, perinatal, and parenteral) (Table 1). For each respondent, the number of correct responses to these three statements was summed to yield a transmission knowledge score; this score could range from 0 to 3, with higher scores indicating more knowledge. Seven statements were used to assess general AIDS knowledge. For each respondent, the number of correct responses to these seven statements was summed to produce a general knowledge score; this score could range from 0 to 7, with higher scores indicating more knowledge. Seven questions were used to assess misperceptions about HIV transmission through casual contact. For each respondent, the number of incorrect responses was summed to produce a misperception score; this score could range from 0 to 7, with higher scores indicating more misperceptions about HIV transmission through casual contact.

The demographic variables examined included age (18 to 49 years and 50 years or older), race ethnicity (White non-Hispanic, Black non-Hispanic, and Hispanic), and education, given that knowledge differences within these categories have been previously reported from the NHIS current health topic on AIDS Knowledge and Attitudes[6,7] and elsewhere.[1,8–14] Data were also analyzed by marital status for males younger than 50 years old because most AIDS cases have occurred in young men.[15] Single men

included those who were divorced, separated, or never married.

To make national estimates, estimates derived from the NHIS sample were weighted to take into account selection probability, nonresponse, and an adjustment to the current US population.[3] Mean scores and proportions were generated with SAS software. Standard errors (SEs) and statistical differences between mean scores were calculated with SESUDAAN, which takes into account the complex sample design of the NHIS.[16] For the comparison of two means, the standard error of the difference (SED) was used to calculate the 95% confidence interval around the difference. All the differences noted in the text were significant at the 0.05 level.

Results

Of the respondents who could be classified into an AIDS incidence area, 12% (n = 2049) resided in an area with a high annual incidence of AIDS, 50% (n = 8625) resided in a medium-incidence area, and 38% (n = 6603) resided in a low-incidence area. Thirty-seven percent of the persons who lived in a high-incidence area were 50 years of age or older compared with 32% and 34% in medium- and low-incidence areas, respectively. Blacks made up 25% of the study group who lived in a high-incidence area compared with 16% in both medium- and low-incidence areas. Eighteen percent of persons residing in a high-incidence area were Hispanic compared with 10% and 4% in medium- and low-incidence areas, respectively. Twenty-three percent of persons living in a high-incidence area had less than a high school education compared with 19% and 21% in medium- and low-incidence areas, respectively. Fifty-one percent of unmarried males who were younger than 50 years of age resided in a high-incidence area compared with 47% and 44% in medium- and low-incidence areas, respectively.

When the estimated overall mean transmission knowledge, general knowledge, and estimated misperception scores for persons classified into the three incidence groupings were compared with estimated scores for persons in areas not classified, no differences were found.

Transmission Knowledge Scores

The estimated mean transmission knowledge score was 2.8 (SE = .01) out of a possible 3 for both the nation and each AIDS incidence grouping. Persons 50 years of age or older had a mean transmission knowledge score of 2.7 compared with 2.9 for those aged 18 to 49 years (SED = .01). Those with less than a high school education had a lower mean score (2.6) than those who had 12 years of education (2.9, SED = .01) and those who had 12 or more years of school (2.9, SED = .01). No differences in scores were noted by AIDS incidence area. SEDs for mean transmission knowledge scores in subgroups within incidence groupings ranged from .03 to .06.

TABLE 2—Mean General Knowledge Scores by Demographic Characteristics and AIDS Incidence Groupings

Demographic Characteristics	General Knowledge Scores[a] AIDS Incidence Groupings: High	Medium	Low	US Total	Maximum Differences in Scores
Total	4.7	4.8	4.8	4.8	0.1
Age:					
18–49 years	4.9	5.0	5.0	5.0	0.1
50+ years	4.4	4.4	4.4	4.4	0.0
Race:					
White	4.7	4.8	4.8	4.7	0.1
Black	4.4	4.4	4.5	4.3	0.1
Hispanic	4.6	4.3	4.3	4.4	0.3
Education:					
<12 years	4.0	4.1	4.1	4.0	0.1
12 years	4.7	4.8	4.9	4.8	0.2
>12 years	5.2	5.1	5.1	5.1	0.1
Marital status:[b]					
Single males	4.6	4.8	4.7	4.7	0.2
Married males	4.9	4.8	5.0	4.9	0.2

[a]Mean number of correct responses out of a possible seven.
[b]Includes males younger than 50 years old.

General Knowledge Scores

The estimated mean general knowledge score for the nation was 4.8 (SE = .02) out of a possible 7, and overall, scores were nearly identical in each incidence grouping (Table 2). However, for the nation and within each incidence grouping, differences were observed for age, race ethnicity, education, and marital status for males. By level of education, the racial/ethnic differences remained except for Hispanics with 12 or more years of school. Hispanics who lived in a high-incidence area had a higher mean general knowledge score (4.6) than those in areas of medium (4.3, SED = .10) or low (4.3, SED = .14) incidence. SEDs for mean general knowledge scores in subgroups within incidence groupings ranged from .04 to .14.

Misperception Scores

The estimated mean misperception score for the nation was 2.9 (SE = .03) out of a possible 7. Overall and within each incidence grouping, differences were observed for age, race ethnicity, education, and marital status for males (Table 3). The effect of race/ethnicity on misperception scores remained after controlling for education except for Hispanics with 12 years of school.

Overall, persons who lived in a high-incidence area had a higher mean misperception score (3.1) than those who lived in areas of medium (2.8, SED = .09) or low (2.8, SED = .09) incidence. Persons 50 years of age or older who lived in a high-incidence area had a higher mean misperception score (3.6) than those in the same age group who lived in areas of medium (3.3, SED = .13) or low (3.3, SED = .13) incidence. This pattern was not observed in younger adults. Persons who had 12 years of education and who lived in a high-incidence area had a higher average score (3.3) than persons with the same number of years of education who lived in areas of medium (3.0, SED = .12) or low (2.9, SED = .08) incidence, but no trends were observed among those with more or with less education. Single men in a low-incidence area had a higher average misperception score (2.8) than single men in a medium-incidence area (2.5, SED = .14). Married men in a high-incidence area had a higher average misperception score (3.0) than married men in a low-incidence area (2.6, SED = .16). SEs for mean misperception scores in subgroups within incidence groupings ranged from .06 to .25.

TABLE 3—Mean Misperception Scores by Demographic Characteristics and AIDS Incidence Groupings

Demographic Characteristics	Misperception Scores[a] AIDS Incidence Groupings				
	High	Medium	Low	US Total	Maximum Difference in Scores
Total	3.1	2.8	2.8	2.9	0.3
Age:					
18–49 years	2.8	2.6	2.6	2.7	0.2
50+ years	3.6	3.3	3.3	3.4	0.3
Race:					
White	2.8	2.6	2.7	2.8	0.2
Black	3.4	3.4	3.4	3.5	0.0
Hispanic	3.2	3.4	3.4	3.3	0.2
Education:					
<12 years	4.1	3.9	3.9	4.0	0.2
12 years	3.3	3.0	2.9	3.0	0.4
>12 years	2.3	2.3	2.2	2.3	0.1
Marital status:[b]					
Single males	2.6	2.5	2.8	2.7	0.3
Married males	3.0	2.8	2.6	2.8	0.4

[a]Mean number of incorrect responses out of a possible seven.
[b]Includes males younger than 50 years old.

To test whether scores for counties with a very high annual incidence rate of AIDS were in any way remarkable, the three MSAs with the highest incidence rates were compared with the rest of the classifiable counties. The mean transmission knowledge scores were identical (2.8). However, the mean general knowledge score for the three highest MSAs (4.5) was significantly lower than that for the remainder of the counties (4.7, SE = .04), while the mean misperception score for the three highest MSAs (3.3) was significantly higher than that for the other counties (2.8, SE = .11).

Discussion

An effective educational program is a crucial part of the public health response to AIDS. The information from the continuing NHIS AIDS Knowledge and Attitudes survey has been useful for guiding national educational efforts and for evaluating specific campaigns such as the CDC's "Understanding AIDS" brochure, which was mailed to every US household in spring 1988.[17]

Disease knowledge and risk perceptions in an area might be hypothesized to be either positively or negatively associated with disease incidence in a cross-sectional survey such as the NHIS. Ignorance of disease risk factors and of preventive measures might lead to adoption or continuance of behaviors that place an individual at risk, which, in turn, results in high incidence rates for the disease. Alternatively, in areas where a disease is common, effective public health efforts to educate the population could lead to an increasing knowledge of the disease. Misperceptions about transmission might be exacerbated by the disease frequency in an area if they are fueled by the public's concern about the greater probability of coming in contact with infected persons in a high-incidence area. On the other hand, misperceptions may be lower in a high-incidence area if public health education has been successful.[18]

This analysis of the 1988 NHIS AIDS Knowledge and Attitudes survey shows that knowledge about the major modes of HIV transmission (i.e., sexual, parenteral, and perinatal) was high in all demographic groups in the United States. Overall, the nation's general knowledge about AIDS and HIV infection was high, and misperceptions about the risk of transmitting the virus through casual contact were few. This confirms data from numerous national, state, and local studies.[1,6,7,12,14,19–22]

Previous studies have identified older persons, Blacks, Hispanics, and those with fewer than 12 years of education as being less knowledgeable about AIDS,[1,6,8–14] a finding also supported by our study. Our report further demonstrates that the demographic determinants (i.e., age, race ethnicity, education) of knowledge and the misperception scores were the same within each AIDS incidence area as they were nationally.

Among persons living in a high incidence area for AIDS, higher misperception scores were noted overall and for several subgroups: persons 50 years of age or older, persons with 12 years of education, and married men. Some of these differences may be explained by the proportionately higher number of older persons, minorities, and persons with less than a high school education who resided in high-incidence areas. However, the absolute differences in misperception scores among those living in areas of high, medium, or low AIDS incidence were modest compared with differences attributable to age, race ethnicity, and education. In addition, because of the large sample size of the NHIS, some differences that were statistically significant were in magnitude quite small and probably of little practical importance. We did note larger differences when we focused on areas of extremely high AIDS incidence; however, these differences may have been due more to the distribution of certain demographic characteristics than to incidence. An inadequate sample size prevented us from further stratifying the data. National public opinion surveys conducted between 1983 and 1986 also found that misperceptions about AIDS showed some geographical variation.[1] Perhaps these differences lessened by 1988, when the NHIS data used in this report were collected.

Our overall findings of no differences in transmission and general knowledge scores in areas that differed markedly in the annual incidence of AIDS is in contrast to a recent finding in a study of gay men, in which bar clientele in areas with high AIDS prevalence were more knowledgeable about AIDS than men in low-prevalence areas.[18] Homosexual men are at especially high risk, and findings for them may not apply to other groups. The NHIS AIDS Knowledge and Attitudes survey does include a general question assessing whether respondents have engaged in any of various HIV risk behaviors; however, only 2% reported engaging in such behaviors, and this group was too small to analyze in this study.

Because AIDS incidence data are not available for all US counties, we could not classify 41% of the NHIS sample. Therefore, the findings from this report may not apply directly to these areas. However, areas not included are disproportionately nonmetropolitan (57%) and presumably of low incidence. Approximately 25% of nonclassifiable areas are in states with low incidence rates (fewer than 5 cases per 100 000 population), even in metropolitan

areas. In addition, general knowledge about AIDS in areas that were not classifiable did not differ from such knowledge in areas that could be classified; the latter included areas with a wide range of population densities and presumably a wide cross-section of the American public.

The observation that AIDS transmission knowledge and general knowledge scores in this national survey are similar for various demographic groups in the United States, regardless of the incidence level of AIDS, suggests that the ability of educational messages to reach and be absorbed by individuals nationwide depends less on whether those individuals currently live in an area where the annual incidence of AIDS is high than it does on demographic and other variables. Our finding, which shows the influence of age, race, ethnicity, and education on knowledge and perceptions about AIDS in geographic areas throughout the United States that vary by threefold or more in annual AIDS incidence, reinforces the importance of new and continued efforts to improve knowledge among older persons, minorities, and the less educated in all parts of the country. □

HIV Instruction, HIV Knowledge, and Drug Injection among High School Students in the United States

Deborah Holtzman, PhD, John E. Anderson, PhD, Laura Kann, PhD, Susan L. Arday, MHS, Benedict I. Truman, MD, MPH, and Lloyd J. Kolbe, PhD

ABSTRACT

Background. The prevalence of HIV-related behaviors and determinants of these behaviors among adolescents in the United States have not been well studied.

Methods. To determine the prevalence of HIV-related drug behaviors and to assess the effects of HIV-related school-based instruction and HIV knowledge on these behaviors, data were analyzed from a 39-item, self-administered questionnaire completed by a probability sample of all students in grades 9 through 12 in the United States.

Results. Usable responses were obtained from 8098 students. Of these, 2.7% (95% confidence interval [CI] = 2.3–3.2) and 1.7% (95% CI = 1.3–2.1) reported injecting illicit drugs ever and during the past year, respectively. Corresponding prevalences of needle sharing were 0.8% (95% CI = 0.5–1.1) and 0.5% (95% CI = 0.3–0.7). Regression analysis revealed that students with higher knowledge scores were less likely and males more likely to have ever injected drugs. HIV knowledge was similarly associated with other outcome measures of drug-injection behavior. Although HIV instruction did not directly influence drug-injection behavior independently of demographic characteristics, it was positively associated with HIV knowledge.

Conclusions. While these results do not establish a causal relationship, they suggest that HIV knowledge and school-based instruction may play a role in maintaining low levels of drug-injection behavior among high school students. (*Am J Public Health.* 1991;81:1596–1601)

Introduction

This article describes the prevalence of self-reported illicit drug injection among high school students in the United States and examines the relationships among school-based instruction about human immunodeficiency virus (HIV), HIV knowledge, and drug-injection behavior. Although the incidence of acquired immunodeficiency syndrome (AIDS) in US adolescents is not as high as it is in adults and children, each of these groups has experienced a rapid rate of growth in the cumulative incidence of the disease in the last decade.[1,2] Because of the long latency period for HIV, which may average 10 years or more,[3] it is also likely that many of the 20- to 29-year-olds diagnosed with AIDS, who account for 20% of all cases nationwide,[4] were infected with HIV during adolescence. Indeed, many adolescents engage in behaviors that place them at risk for HIV infection. As of July 1990, 40% of the AIDS cases in the United States reported among 13- to 19-year-olds resulted from sexual transmission of HIV, 11% of cases reported histories of intravenous (IV) drug use, and another 4% reported both risk behaviors.[4]

In national surveys, reported rates of sexual intercourse among 17- to 19-year-old, never-married males in metropolitan areas increased from 65.7% in 1979 to 75.5% in 1988.[5] In similar surveys of US females, the rates of premarital sexual intercourse among 15- to 19-year-old adolescents living in metropolitan areas increased from 43.4% in 1979 to 45.2% in 1982.[6] Further, a 1979 survey of adolescent females revealed that their mean age at first intercourse was 16.2 years and that 16% of the sample reported four or more sexual partners.[7,8] In a 1989 nationwide survey, 58.5% of 9th- through 12th-grade students had had sexual intercourse, and of these, 40.4% reported four or more partners. In addition, 23.3% of the students who ever had sex reported that they never used a condom when they had sexual intercourse.[9]

IV drug use has also been reported in surveys of youth, but the extent and nature of illicit drug-injection behavior among adolescents has not been well studied. Surveys of IV drug use in relatively small or geographically limited populations of adolescents have shown considerable variation in rates, ranging from 0.1 to 6.3%.[10–15] How prevalent, then, is IV drug use among adolescents in the United States? And equally important, what factors influence this behavior?[16]

Several surveys of HIV-related knowledge, attitudes, and behaviors among adolescents have been reported,[5,10–15,17,18] but only one was nationwide in scope,[13]

only a few assessed risk behaviors for HIV infection,[10-12,14,15] and fewer still have analyzed possible determinants of these behaviors.[11]

As part of a system of surveys for collecting school-based data, the Centers for Disease Control conducted the Secondary School Student Health Risk Survey (SSSHRS) in April and May of 1989. The SSSHRS was the first survey to collect data about HIV-related knowledge, beliefs, and behaviors among a nationally representative sample of US students in grades 9 through 12. Two variables that may be possible determinants of behavioral risk reduction—HIV instruction and HIV knowledge—were measured by the survey. The SSSHRS also collected data about sexual activity and illicit drug injection. This report focuses on the latter.

First, we examined the prevalence of injected drug use among high school students. Second, we examined whether students who had received classroom instruction about HIV and who had a greater level of HIV knowledge were less likely than other students to have injected drugs or shared needles. With this information we can better plan and evaluate our HIV educational efforts for adolescents.

Methods

Study Population

The sampling frame, which consisted of all US public- and private-school students in grades 9 through 12, was divided into 1921 primary sampling units (PSUs) and stratified by region and urbanicity. Fifty PSUs were selected and, from these PSUs, 50 counties were selected. From the 50 counties, 122 schools were selected. At each stage, the sample was selected with probability proportional to the size of the 9th through 12th grade enrollment. Heavily Black and Hispanic areas were oversampled. Within participating schools, one or two classes of a required subject were randomly selected.

Data Collection

Representatives from numerous federal, state, and local education agencies and experts in HIV and reproductive health behaviors were involved in developing the survey instrument. Personnel were trained to coordinate on-site data collection, and special measures were taken to protect student anonymity. A 39-item questionnaire was designed to be self-administered in the classroom. Five broad groups of variables were assessed by the questionnaire: demographic characteristics, HIV instruction, HIV attitudes, HIV knowledge, and HIV-related risk behaviors. Variables used in the current analysis are described in more detail below.

HIV Instruction, Knowledge, and Behavior. A single question, answered yes or no, was used to measure HIV instruction. Students were asked, "Have you been taught about AIDS/HIV infection in school?" Seventeen items measured HIV knowledge. Students were asked about such factors as modes of HIV transmission and how to reduce risk for HIV infection. Based on the number of correct responses to the 17 items, a score was computed for each respondent, with equal weight given to each question. Drug-injection behavior was assessed by four dichotomous dependent variables. Students were asked if they had done the following: (1) ever injected illicit drugs, (2) injected illicit drugs in the last year, (3) ever shared needles, or (4) shared needles in the last year.

Data Analysis

Two separate multivariate analyses were conducted to examine relationships among HIV knowledge, HIV instruction, and drug-injection behavior. Using multiple linear regression, HIV knowledge was regressed on HIV instruction, while controlling for age, sex, racial or ethnic group, and the interactions between HIV instruction and sex, and between HIV instruction and racial or ethnic group. Using stepwise multiple logistic regression, each of the four drug-behavior variables was regressed on HIV instruction and HIV knowledge, controlling for the same background characteristics. There are theoretical and empirical reasons for including both HIV instruction and knowledge in the models. Theoretically, for instruction to have an effect on drug behavior it would likely work through some other mechanism, such as knowledge or attitudes. Without knowledge, then, the model would be improperly specified, and would bias the effect of instruction on drug behavior. In addition, a comparison of the model with knowledge and without knowledge showed that the effect of HIV instruction on drug behavior did not change. A further complication arises, however, if HIV instruction and HIV knowledge are highly correlated. This was examined by the authors and the correlation between the two variables was found to be relatively low ($r = .21$), suggesting that multicollinearity was not a problem in the analysis.

Since very few students reported having shared needles within categories of racial or ethnic group and HIV instruction, the effect of these interactions on sharing needles could not be evaluated. Additionally, because the interactions between knowledge and each demographic characteristic and between HIV instruction and age were all highly correlated ($r > .82$) with at least one of the main effects, these terms were excluded from all models. All main effects, regardless of the level of significance, were retained in the models when the interaction term was significant.[19]

All data were weighted to compensate for nonresponse within categories of age, grade, and sex, and the fact that not all students were sampled with the same likelihood. The SAS programming

White	60.9	58.4
Black	11.6	13.2
Hispanic	11.0	11.6

language was used to conduct the analyses,[20] and statistical tests and confidence intervals were based on the procedures SURREGR, SESUDAAN, and RTILOGIT, which take into account the complex sample design.[21–23] Results were considered significant if the *P* value for the calculated statistic was less than or equal to .05.

Results

Of the 122 schools selected, 99 (81%) participated. Selected schools and participating schools were compared by region, metropolitan or nonmetropolitan area, and racial or ethnic group (Table 1). Only small differences were observed within each category, suggesting that school-level nonresponse did not greatly bias the sample.

Of selected students, 10% did not receive parental permission to participate and an additional 7% were absent when the survey was administered and on the scheduled make-up day(s). Usable questionnaires were received from 8098 (83%) of the eligible sample. Based on the school- and student-level response, an overall response rate of 67% was obtained.

Participants were fairly evenly distributed by grade and sex (Table 2). The weighted percentages of White, Black, and Hispanic students who participated were similar to estimates of the racial and ethnic distribution of 9th- through 12th-grade students in the United States. For the US population of students in these grades, the estimates were 70.8% White, 15.5% Black, and 8.9% Hispanic.[24] (Calculations for general population estimates of high school students were also based on unpublished data from US Bureau of the Census, Annual Projections of the Population by Age, Sex, Race, for the United States: 1983 to 2080, Hispanic by race data, July 1, 1988.)

Slightly over half (53.7%) of those surveyed said they had received instruction in school about AIDS and HIV infection (Table 3). Significant differences in the proportion of students reporting HIV instruction were found by age and grade only. Students who were 17 or more years of age were less likely than 15- and 16-year-old students to have received HIV instruction ($P < .05$), and 12th-grade students were less likely than 10th- or 11th-grade students to have received instruction ($P < .05$).

For all students, an average of 14.5 knowledge items were answered correctly (range = 0–17). The vast majority of students knew that AIDS/HIV infection is transmitted during sexual intercourse (97.7%), by sharing needles (98.9%), and perinatally (90.7%). Most also knew that HIV infection is not transmitted by casual contact. Students were less informed about transmission of the virus in other ways; only 64.0% knew the virus could not be transmitted by donating blood, and only 45.1% knew the virus could not be transmitted by insect bites.

When asked about drug-injection behavior, 2.7% of students reported having ever injected illicit drugs, and 0.8% reported having ever shared needles (Table 4). The rate of ever injecting drugs was higher for males than for females (3.7% vs 1.8%, $P < .05$). Differences in drug-injection behavior by racial or ethnic group were not statistically significant.

The reported rates of ever injecting drugs showed a clear decline from grades 9 to 12, and significant differences were observed between 9th- and 12th-grade students ($P < .05$). No significant differences, however, were found by age group. Finally, students who reported having been taught about HIV were less likely than those who reported no instruction to have ever injected drugs ($P < .05$).

Results of logistic regression analysis showed that HIV knowledge, being male, and the interactions between HIV instruction and being male and between HIV instruction and being Black all had significant effects on ever injecting drugs (Table 5). The greater the level of knowledge, the less likely students were to report ever injecting drugs. Males were more likely than females to have injected drugs, although males who had received HIV instruction were less likely to have injected

drugs when compared with males who had not received HIV instruction and with females. Further, Black students who had received HIV instruction were less likely to have ever injected drugs when compared with Blacks who had not received instruction and with students of other racial or ethnic groups. No significant direct effect of HIV instruction on ever injecting drugs was found.

Drug injection in the last year was significantly associated with level of HIV knowledge and sex (Table 6). The greater the level of knowledge, the less likely students were to have injected drugs in the last year, but, as with lifetime drug-injection behavior, males were significantly more likely than females to report the behavior in the last year. Again, there was no direct effect of HIV instruction on last year drug-injection behavior.

Similar results were found for those who reported ever sharing needles or sharing needles in the last year (Tables 7 and 8). The greater the level of knowledge, the less likely students were to have ever shared needles or to have shared needles in the last year. While the difference between males and females in ever sharing needles was not quite statistically significant, males were significantly more likely than females to have shared needles in the last year.

In additional analyses, not shown here, we found that students who reported injecting drugs and sharing needles were more likely to report multiple sexual partners (defined as two or more) and to report never using condoms when having sex.

TABLE 8—Final Parameter Estimates for Regression of Sharing Needles in the Last Year on HIV Instruction, HIV Knowledge, and Demographic Characteristics, 1989 Secondary School Student Health Risk Survey

Variable[a]	b[b]	Standard Error of b
Intercept	−1.040	0.790
HIV knowledge*	−0.371	0.063
Male*	0.950	0.435

[a]Reference category for male is female.
[b]Unstandardized regression coefficient.
*$P < .05$.

Also, in additional regression analyses, we found that within the subgroup of students who reported multiple sexual partners and within the subgroup of those who reported never using condoms, HIV instruction and knowledge had the same effect on ever injecting drugs and ever sharing needles that was demonstrated in our analysis of all students. The greater the level of knowledge, the less likely students were to report ever injecting drugs and ever sharing needles.

Furthermore, within the subgroup of students with multiple sexual partners, Black students who had been taught about HIV were less likely than Black students who had not received instruction and students of other racial or ethnic groups to report ever injecting drugs. Finally, within the subgroup of students who reported never using condoms, males who had received HIV instruction were less likely than noninstructed males and females to have ever injected drugs. Thus, even for students who engage in risky sexual behaviors, HIV knowledge and, for some students, HIV instruction continue to exert a positive influence on HIV-related drug behavior.

Finally, we examined the relationship between each HIV knowledge item and each of the drug behavior variables to see which items might be most predictive of the behaviors. Most highly negatively correlated with ever injecting drugs and ever sharing needles were correct responses to four items that asked about transmission of HIV through sharing needles and sexual intercourse.

Although HIV instruction did not have a significant direct effect on drug-injection and needle-sharing behavior independent of demographic characteristics, it was significantly associated with HIV knowledge (Table 9). When we controlled for demographic characteristics, students who had received HIV instruction were more likely than students who had not received instruction to have a greater level of HIV knowledge. Specifically, students who received HIV instruction in school answered, on average, almost one additional item correctly.

Age, being male, and racial or ethnic group were also significantly related to HIV knowledge. Students who were older and those who were White were more likely to have a higher level of knowledge about HIV, compared to younger students and those in the other racial or ethnic groups. Males, on the other hand, had a significantly lower level of knowledge about HIV than females did.

Discussion

Although the results of our survey showed that illicit drug-injection behavior was not common among the nation's high school students, it was reported by some students—more frequently by males and by those who had not received HIV instruction in school. The percentage of high school students who have injected illicit drugs is a cause for concern, however. If 2.7% of the nation's 9th- through 12th-grade students have injected drugs and 0.8 percent have shared needles, then approximately 345 100 and 102 200,[24] respectively, may have already engaged in behaviors that can quite efficiently transmit the virus that causes AIDS.

Moreover, students who inject drugs may be less likely to remain in school than students who do not. The observed decrease in drug-injection behavior by grade, and to some extent by age, could be attributed to the fact that dropout rates increase with grade—a phenomenon that, in turn, may be exacerbated by drug use. Indeed, one study showed a higher rate of drug use among dropouts than among in-school youth.[25]

When HIV instruction and demographic characteristics were taken into account, HIV knowledge was found to be associated with lower levels of drug-injection and needle-sharing behavior. And although males were more likely than females to report these behaviors, the results suggested that males who had received HIV instruction were less likely than uninstructed males to have ever injected drugs. Similarly, Blacks who had received HIV instruction were significantly less likely to report ever injecting drugs than were Black students who had not received instruction and students of other racial and ethnic groups. These results are particularly promising, because Blacks and males in the United States are disproportionately affected by AIDS.[26–28] Further, HIV instruction was significantly associated with an increased level of HIV knowledge among students, which in turn, was associated with lower levels of drug-injection and needle-sharing behavior.

Although these results have important implications for HIV education, some limitations of the data are important to consider. First, because the SSSHRS was a cross-sectional survey, causal relationships among the variables cannot be established. In addition, other variables that may have an effect on drug-injection behavior could not be accounted for in the analysis—for example, educational performance, socioeconomic status, peer norms, or drug availability. Also, because the data were self-reported, under- or overreporting may have occurred, especially given the sensitive nature of the behavior questions. Finally, since the data are school-based, the results can be generalized only to adolescents who attend school.

The data, however, were from a large, population-based sample; a number of variables were available for control; and more than one type of behavioral outcome was assessed. The prevalence of drug-injection behavior among secondary school students in the United States found by the SSSHRS was similar to other estimates of drug injection in this population,[12,15] and the analysis demonstrated that HIV knowledge does affect this behavior. In a study of adults, HIV knowledge was also shown to be a predictor of behavioral risk reduction.[29] Further, the effect of knowledge was significant for each indicator of drug-injection behavior in the current analysis. A similar effect of HIV knowledge was found when it was examined in relation to sexual behavior and condom use in the SSSHRS; that is, the greater the level of knowledge, the fewer the number of sexual partners and the higher the level of condom use.[9] Our results were also strengthened by an association between increased levels of HIV knowledge and lower levels of reported drug-injection and needle-sharing behavior within two subgroups of students at increased risk of HIV—those who reported two or more lifetime sexual partners and those who reported never using condoms when having sex.

White[a]	1.047	0.277

[a]Reference categories for HIV instruction, male, and White are no HIV instruction, female, and other racial or ethnic group, respectively.
[b]Unstandardized regression coefficient.
[c]$P < .05$.

In our survey and in others, adolescents were quite knowledgeable about AIDS and HIV infection—at least about the major modes of HIV transmission.[10–15,17,18] But few previously reported studies focused on behavior, and only one that we found,[11] which was limited to a single high school, also examined determinants of HIV-related behaviors in youth.

While our analysis showed a relationship between knowledge and HIV-related drug behavior, we do not want to imply that knowledge is the only factor that may be related to behavioral change. Other factors, not measured in the current analysis, may be important predictors of behavioral change in addition to knowledge, for example, certain attitudes, social skills and support, perceived norms, and perceived efficacy in avoiding risks.[30] Thus, it should not be inferred from the results that educational programs designed to increase HIV knowledge alone will have an effect on behavior. But, while other factors that may affect drug-injection behavior need to be investigated, our results suggest that knowledge about HIV may be one factor in the complex process of behavioral change. Comprehensive school health education programs that increase knowledge, as well as specific skills that may influence HIV-related behavior, could be an important means to help prevent the further spread of HIV infection among our nation's youth. □

Needle Sharing in The Netherlands: An Ethnographic Analysis

Jean-Paul C. Grund, PhD, Charles D. Kaplan, PhD, and Nico F. P. Adriaans

ABSTRACT

Background. Needle sharing has been reported to be the main cause of the rapid spread of the human immunodeficiency virus (HIV) among injecting drug users. Risk behaviors such as needle sharing are, however, the end result of complicated interaction patterns in drug user networks, which have their specific rules and rituals, and larger social structures and official drug policy.

Methods. To study these interaction patterns we examined the drug administration rituals of heroin addicts in Rotterdam, The Netherlands. Intensive ethnographic descriptions were collected by participant observation.

Results. In less than 10% of the observed self-injections unsafe syringes were used. In 68% of the self-injections new, sterile syringes were used. Needle sharing as a planned sequence was not observed. Sharing was determined primarily by the availability of syringes, experience with the injecting ritual, and drug craving. In all observed needle-sharing events, subjects were aware of the risks involved and undertook efforts to clean the injection equipment.

Conclusions. In contrast to psychological approaches aimed at reducing individual "risk behavior," these findings suggest that HIV prevention can be made more effective if active drug injectors are organized to help themselves and their peers prevent high-risk exchange situations. (*Am J Public Health.* 1991;81:1602–1607)

Introduction

Injecting drug users (IDUs) are at risk for the human immunodeficiency virus (HIV) and other viral and microbacteriological infections through their use of contaminated syringes and needles,[1,2] generally termed "needle sharing." (Throughout the text, unless otherwise specified, the term needle sharing refers to the sharing of both needles and syringes.) In The Netherlands, only a minority of drug addicts inject. Most Dutch addicts smoke their heroin and cocaine from aluminum foil (chinesing or chasing the dragon).[3] Compared with neighboring countries and the United States, the availability and quality of heroin and cocaine on the Dutch illegal market have stabilized over the years at relatively high levels and these drugs may be purchased at moderate prices.[4] These economic factors were prerequisites for the diffusion[5,6] of the Asian practice of heroin smoking into the Dutch heroin-using population. However, the drug-injecting minority has not been overlooked by the Dutch government and helping organizations. Since the mid-1970s risk reduction and harm minimization strategies have been in place for all addicts.[7,8]

Few HIV seroprevalence studies have been conducted in The Netherlands. In a selected group that may not represent all drug users in Amsterdam, van den Hoek et al. found a HIV seroprevalence of 33% at entry into the study.[9] A seropositivity rate of 4.8% was found in a nonrepresentative sample from outside the large urban centers.[10] In a Rotterdam study on a sample of "extreme problematic drug users" in methadone maintenance, seropositivity was found to be 9.7% in 1986 and 6.5% in 1987.[8] As a comparison, among methadone clients in Rotterdam, self-reported lifetime prevalence for hepatitis is 19%, for gonorrhea 24%, and for syphillis 5%.[11]

Most of the current acquired immunodeficiency syndrome (AIDS) behavioral research consists of studies relating HIV/AIDS prevalence to HIV-risk factors, such as needle sharing. Few published studies describe what actually happens in such needle-sharing events. This article presents an ethnographic study of the patterns and circumstances of drug use and attempts to determine what variables are associated with risk behaviors such as needle sharing.

Methods

Data collected by self-report techniques may be highly biased if they reflect socially undesirable or criminalized behavior. Ethnographic field observations provide an opportunity to overcome the potential disadvantages of questionnaires or interviews by directly recording behaviors, thus reducing the biases of memory, self-perception, fear, and mistrust.[12] Nevertheless, the validity and generalizability of ethnographic study findings have been questioned.[13] The researcher's presence can alter the context and behaviors of the study group. However, the collective experience of the ethnography of socially undesirable behaviors indicates that with

due care and time the researcher can become "part of the furniture."[13] Group members live within well-established traditions that structure and limit their actions. While the presence of the researcher may introduce a new constraint, the weight of tradition generally prevails.[14] The validity of ethnographic data can be further improved through appropriate controls on site and subject selection, observational strategies and protocols of data recording, and the development of trust between researchers and study subjects.[15]

The data to be presented were collected between February 1988 and April 1989 as part of an ongoing Rotterdam research project of the drug-taking rituals of heroin addicts. The principal methodology was "street" ethnography. Intense participant observation of addicts' self-administration of heroin and cocaine at dealing places, their homes, and public places was conducted. This observation was structured using an observational protocol of endogenous and exogenous cues pertaining to the heroin rituals of injecting and smoking.[16] The Appendix presents a summary table of the inventory of events indexed by the protocol.

Trust, acceptance, and credibility were developed by a field research team consisting of a community field worker (a respected ex-addict) and the principal investigator, both of whom were known to the participants prior to the study. During informal conversations with drug users, the project's goals were discussed. Other than providing an occasional sandwich or cup of coffee, participants received no fees. Enduring relationships have developed with some study participants who eventually became "key informants" and provided important supplemental information.

No structured interviews were held; when possible, additional information was collected from informal conversations. Detailed fieldnotes of 95 rituals were recorded. In 44 observations, subjects were smoking; in 2, subjects were snorting; and in 49, subjects were injecting.

The observations were recorded in the afternoon (94%) and early evening (6%) in two neighborhoods of Rotterdam characterized by high drug activity; 93% of the observations were recorded at 14 different houses where addicts live, deal drugs, or both. In 53% of the observations those houses were legally rented, in 9% they were subleased, and in 38% the house was squatted. The remaining observations were recorded in public places and abandoned buildings. All locations were initially selected through neighborhood exploration and key-informant information. At times, the research team accompanied participants on their daily rounds. In this way they were also introduced to new dealing places, using places, and private homes. During the fieldwork, some of the dealing places were closed down by the police. Although these "busts" caused some turmoil, they did not seem to have a significant impact on drug use. New places quickly opened up, sometimes on the same day at the same address. Often the researchers were introduced to the owner of a new address by a key informant. By following the dynamics of the drug scene, most of the neighborhood dealing sites could be observed.

Fieldnotes were produced independently by the researchers after each fieldwork session or the following morning, based on short notes taken during or immediately after the observations. The fieldnotes were processed using ETHNOGRAPH, a computer program for the analysis of qualitative data.[17] The data were coded in line with the observational protocol; the codes evolved constantly during the data collection and concurrent coding process. In order to complement this qualitative analysis, the data were quantified by counting significant events and by recording available demographic and background characteristics of the subjects. The numbers presented in this article were generated through these quantifications and are intended to support the qualitative analysis. Although this selected sample may not represent all drug users in Rotterdam, this is a common feature in most studies which examine "hidden" populations.

The total number of subjects contacted was 192 (168 males and 24 females). By comparing independent field-worker estimates, ages of 106 subjects could be specified: 30% were 25 years or younger, 50% were between 25 and 35, and 20% were over 35. This distribution resembles that found in the Rotterdam registration system of heroin addicts in methadone treatment (RODIS).[11] For 23% of the subjects injecting was the main mode of drug administration, while the remaining 77% smoked; 96% used both heroin and cocaine. The field work established that both heroin and cocaine were available at all dealing addresses. That cocaine has become increasingly important to Dutch heroin addicts is verified by the RODIS system, in which 72% of the treatment population uses cocaine.[11]

TABLE 1—Status and Origin of Syringes in Observed Self-Injections (N = 44)

Status and Origin	n	%
New		
In possession of subject	9	21
Received at place of injection	21	48
Used		
In possession of subject	10	23
Received/found at place of injection	2	5
Received from other intravenous drug user	2	5

Results

Sharing behaviors were found to be frequent and important events for the drug users observed in this study. The sharing of valued things such as housing, food, and clothing is an everyday occurrence tied to survival needs in extreme circumstances. The sharing of drugs fits into this wider pattern of daily interaction and exchange[18] and has been observed for both IDUs and non-IDUs. Among IDUs this interaction pattern may have important implications for HIV transmission.[19] The sharing of drug paraphernalia was also observed: at some addresses spoons, water containers, and lemon juice were available for common usage, and some drug users shared their knives or lighters upon request. However, needle sharing as a planned or stereotyped sequence in which two or more people share, one after the other, the only available syringe was never observed. Most drug users seemed aware of the risks and consequences of needle sharing.

In 68% of self-injection events, a new syringe was used. In 23% IDUs reused their own syringe. In less than 10% of the self-injections, a potentially unsafe syringe was reused (Table 1). Used syringes that were found or received from others were not adequately cleaned (i.e., cleaned with water only). The unsafe self-injections were recorded at addresses where injecting was permitted and in a public place. Because most houses don't allow injecting, IDUs used their drugs in private settings more often than smokers. These house rules may prevent needle sharing. However, some IDUs let their friends and acquaintances inject at their place, sometimes in return for a "taste" of the drug. At some of these using places and at some of the dealing places that allow people to inject, clean syringes supplied by an out-

reach and needle exchange program[20] were dispensed as illustrated in the following fieldnote.

> **1. "Is that an old spike you want to use?"** Although it isn't stated directly, Karel agrees on Jerry taking a shot at his place. Jerry wants to shoot up pure cocaine. He puts his spike on the table and asks Karel for a spoon. Karel asks: "Is that an old spike you want to use?" Jerry: "Well, old, I've used it one time before, so it's still good to use." Karel: "I've got some new ones left from the exchange." He gives a syringe to Jerry asking "You want some more for tonight or the weekend?" Jerry: "If you can spare them I'll take some with me." Karel gives him four syringes.

For many IDUs a strong incentive exists to frequent those places where clean (and sharp) syringes are freely available. Nonetheless, despite the availability of syringes, there were times when we observed IDUs in situations of heightened needle-sharing risk. In those cases, traditional subcultural sharing norms conflict with the more recent norms regarding safe use. The following fieldnote recorded at the "shooting room" of a dealing address documents such a situation.

> **2. "Don't be afraid, I've got no AIDS."** From the corner where she's still busy with the needle in her hand Anja asks: "Do you have a new syringe for me?" Eric answers, "No, this is the only one I got. I was lucky, one minute before the pharmacy closed I bought it." Then Anja asks: "Can't I use it when you're finished. I can't use these anymore," pointing at the syringes laying around her on the floor. "They're all blunt, I can't hit a vein," she says as if she's crying or starting to cry. "Or let me only use the needle then. Please let me, I will clean it for you. Don't be afraid. I've got no AIDS. I've been tested recently at the methadone program." Eric still refuses: "I would like to help you but it's the only one I've got. I never lend out my spike to someone else, nobody, not when I have to use it myself again. When I'm not using it again it's their own risk."

Although needle sharing did not take place, the fieldnote illustrates the often emotional pressure to share a syringe. In this case, in spite of the pressure Eric decided in the interest of his personal health and against the norm of sharing. Nevertheless, the situation can often be tense.

When comparing fieldnotes 1 and 2 the functioning of a variable of perceived responsibility for safe use becomes apparent. In fieldnote 1, the perceived responsibility is given a collective quality. Because the needle exchange program dispenses supplies to IDUs, the possession of ample syringes allows users to reinforce the subcultural norm of sharing, yet in a safe way. In contrast, in fieldnote 2, the perceived responsibility is marked by a strong quality of the "rugged individual junkie" who resists the pressure of community sharing norms by adhering to a personal behavior code.

Although both collective and individual norms of responsibility operate to minimize and manage the risks of needle sharing, there are still situations in which unsafe needle behaviors can be observed. Fieldnote 3, for example, was recorded on the first floor of a house occupied by squatters. The first and third floors of the three-story house were in use. It did not have running water; water was carried to the house in containers from a garage next door. The house was inhabited by a group of older IDUs. At times the group offered shelter to other drug users. They also allowed other drug users to deal heroin, cocaine, or amphetamine in exchange for money or drugs. Occasionally they themselves dealt drugs as was the case in fieldnote 3. This house also was supplied with sterile syringes by the outreach program. However, at the time of observation it was unclear whether there were any new syringes left. Jack (the doorman) let in Billy and Dirk. They all knew one another. Meanwhile some other users went in and out.

> **3. "I don't give a shit about AIDS."** Billy asks Dirk what he wants. "Let's do coke first and then a cocktail," Dirk replies. Billy has a syringe wrapped in aluminum foil. He does not want to wait for a new syringe. Dirk does not have one with him and starts searching. He asks Jack if there are any new ones left. "I don't know," Jack replies. "Maybe upstairs. Ask Karel, he's there." They call Karel several times but he does not answer. Then Dirk finds a syringe in a cupboard. It is unclear who it belongs to. He rinses it with water. He pulls up water twice from a cup he has filled from the water container and squeezes it through the needle. Billy mumbles something about AIDS. Dirk says "Ik heb schijt aan AIDS." (I don't give a shit about AIDS).

Dirk used this syringe two times. First he shared a dose of cocaine with Billy and within 30 minutes he shared a "cocktail" (heroin–cocaine mixture) with Billy and Jack.

In fieldnote 4, two IDUs (Eric and Anja) were in the "shooting room" of a dealing address where injecting is allowed when Leo entered the room. Leo did not come to the address to buy drugs. Eric owed him money and he had heard that Eric was at the address.

> **4. "You have to clean it well."** "I wanted to ask you if you can pay back or otherwise if you could help me with a shot." Leo said. Eric was not able to pay Leo back but offered a cocktail. Leo gladly accepted: "Great man, you don't know how wonderful that is. I'm so glad I didn't miss you here." However, Leo was not in possession of a syringe. Leo asks Eric for a syringe: "I couldn't get a new one. The needle exchange at the Central Station had closed already." Eric tells Leo he only has his own, which he is not willing to share. Then Leo asks Anja if he can take one of her used syringes that are lying in front of her. Anja: "That's useless, they're all blunt, but if you want to try that's okay with me." She picks up several syringes from the floor and looks closely at the needle, comparing one with the other. Finally she makes her decision which one to give to Leo and gives it saying: "You have to clean it well." Leo goes with the syringe toward the sink and cleans it seven or eight times with cold water. To clean the plastic part of the needle, he moves it in such a way that there is some space between syringe and needle. He presses the plunger strongly so the plastic is cleaned under pressure. The water now does not come through the needle but shoots away through the little space between syringe and the plastic needle holder. Leo states: "It must be clean now." Anja tells him: "Don't worry, I'm checked for AIDS recently. I told Eric too."

In fieldnote 5 Mohammed and Abdul had obtained new syringes from the exchange program near the Central Railroad Station before they went to an address to buy cocaine and heroin. They were not allowed to inject at the address, so they went to a small greenhouse in a park. Mohammed prepared the jointly bought drugs. He then divided them by "front-loading," a process in which the solution is first drawn from the spoon into one syringe and then half of the solution is inserted into the hub of the second syringe.[19] Abdul wanted to check to see if the solution was equally divided between both syringes.

> **5. "Don't you trust me?"** Mohammed gives both syringes to Abdul and asks him: "Don't you trust me?" Abdul doesn't answer. He holds the syringes next to each other and stares at them. While doing this he accidentally drops a syringe. The needle falls straight into the ground. Abdul curses and so does Mohammed. Mohammed says, "Now you see what happens. Why don't you believe me?" Abdul picks up the syringe and looks closely at the needle. He asks Mohammed if he still can use it. Mohammed takes the syringe and runs the needle tip over his thumbnail. "No," he says, "there is a burr on it. It's not sharp anymore and it's dirty. You've got to get a new one." Abdul:

"No, I don't go back. Give me yours." Mohammed: "Then you have to wait until I'm ready." After Mohammed has taken his shot he starts cleaning his syringe with the water from the bottle. He puts some lemon juice in the cooker again, pulls it into his syringe, and shakes it so that it mixes with the water. He puts the needle back on it, holds it with two fingers, and presses the water–lemon solution through it as hard as possible. Mohammed explains: "The lemon bites and cleans the needle better." When he's ready, he puts the needle on Abdul's syringe.

Examination of fieldnotes 3, 4, and 5 indicates that needle sharing often is the result of complex and multiple factors. In all the fieldnotes, use of another's syringe was not planned. Rather, an unexpected situation occurred. In fieldnote 3, Billy and Dirk select the particular address because injection is allowed and new syringes are available. However, when they were ready to inject, new syringes were not available. In fieldnote 4, Leo did not have the money to buy drugs but learned by coincidence that Eric, who owed him money, was at the address. He did not have a syringe because the needle exchange had closed for the day. In fieldnote 5, although sufficient prevention measures were taken in advance, an unfortunate accident put one of the users at risk.

In these three fieldnotes an unanticipated change in the situation put the IDUs in the uncomfortable position of choosing between postponing or abstaining from a shot and an unsafe injection. They all chose the unsafe injection although they were well aware of the potential risks of their behavior as evidenced by their rather intensive efforts to clean the used syringes. In fieldnotes 3 and 4, AIDS is associatively mentioned while cleaning the syringes; in fieldnote 5, the use of lemon juice is presented as a cleaning method superior to using water only. However, the effectiveness of AIDS-related knowledge as a protective factor seems to depend on certain specific situational factors.

The significance of one of these situational factors, the intensity of drug craving, deserves special attention. Shortly before an injection, IDUs often become highly aroused. This arousal leads to preoccupation with the sequence that relieves craving. For some IDUs, this sequence begins when the drugs are obtained. For others, the preparation of the injection is the starting point. As one IDU states: "As soon as I put it on the spoon my stomach turns around and I know it's gonna happen, I'm gonna feel that intense rush." In all of the cases presented, postponing the injection would have caused noticeable stress. In fieldnote 3, Billy and Dirk were in high anticipation of an injection. They had already visited the address 30 minutes earlier, expecting to find a dealer working. However, the dealer had just left, so they went to another to buy. When they returned, Billy complained about the trouble they had finding a dealer. Dirk did not bother to see if there were any new syringes upstairs. By this time, the drug craving had become too intense for further deferral. In fieldnote 4, Leo explicitly expressed relief when he was offered an injection. In fieldnote 5, the accident happened only seconds before actual injection. Obviously, Abdul's craving had become so intense that he ignored Mohammed's advice to get another syringe. Furthermore, in all cases cocaine or a mixture of cocaine and heroin was injected. The addition of cocaine to the daily drug-using rituals has been observed in the field to be associated with an intensification of craving and a disruption of stabilized heroin-methadone patterns.

While situational factors play the most important role in needle sharing, certain structural factors can also be seen. One such factor is that of socially learned experience with the injecting ritual, internalized during the IDU career. This experience includes, among other things, protective skills that support safe needle use. The interaction between Billy and Dirk in fieldnote 3 provides an illustration of this factor. Billy, an experienced IDU, went to inject at a place where clean syringes are normally available. Nevertheless, he carried his own used syringe anticipating the absence of new ones. In contrast, Dirk, a novice IDU with no visible needle marks, did not bring a syringe. Immediately after injecting cocaine, he began smoking heroin. He identified himself, not as an injector, but as a smoker, stating: "I'm only shooting now and then, strictly speaking I am a chineser." Irrespective of his AIDS knowledge, Dirk's particular self-deception works against taking the appropriate precautions. His self-perception as a chineser provides a false sense of security that, in turn, leads to blasé attitudes such as "I don't give a shit about AIDS." In fieldnote 5, another case of inadequate socialization is found. Both users were still at an early point in their injecting careers. Mohammed, who reported he had been injecting for about half a year, is instructing the even less experienced Abdul, who was about to take his 10th lifetime injection.

Discussion

Increased availability of drugs is thought to affect consumption by increasing the prevalence of use.[21] Less attention has been given to the harmful effect of decreased availability of drugs. Availability-related variables, such as rising prices, decreasing purity, and unstable supplies can be seen as factors determining the onset of injecting.[22–24] The Dutch experience shows that if availability variables are relatively stable over time, minimizing economic pressure to initiate and maintain injecting, a predominant smoking pattern can develop.[4,25] Thus, injecting can be seen as adaptation to the conditions of decreased drug availability.

The availability of needles also plays a major role in needle sharing.[23,26] Syringes have traditionally been easy to obtain in The Netherlands. Since the AIDS epidemic began, the availability of syringes has increased even more due to the needle exchange programs. Furthermore, in The Netherlands, in contrast to other countries, the possession of injecting equipment has never been illegal.[23,26–28] Risk of arrest discourages IDUs from carrying their personal injection equipment, which limits on-the-spot availability and increases the frequency of sharing drug paraphernalia.

The results of this field study support the hypothesis that when drug and syringe availability is stable and possession of injection equipment is legal, needle sharing decreases markedly. Nevertheless, research in Europe and the United States documents that IDUs are indeed changing their behavior to less risky injecting practices, despite the absence of "Dutch" conditions.[29–31] There seems to be a growing awareness of health risks and a willingness to use drugs in safer, more responsible ways. Our field research found only limited incidence of irresponsible behavior in inexperienced IDUs or those experiencing craving intensified by cocaine. Several recent studies have shown a relationship between cocaine use, risk behaviors, and HIV-serostatus.[32,33] Paralleling other studies, our results show that, even under optimal conditions, IDUs can and do get into situations in which sterile injection equipment is not available. In contrast with novice IDUs, experienced injectors are likely to be more competent in managing such situations.[29,34]

In numerous studies, the social organization of the drug subculture has also been associated with needle sharing. Drug users are often organized in small friendship groups.[35,36] These friendship groups

are often linked in networks whose main activity is to obtain and distribute money and drugs,[35,36] which are often shared and used along with other necessities of life. Sharing and the reciprocal aid it promotes provide a practical and emotional balance to the daily hardship of addict life. In the pre-AIDS era, needle sharing fitted snugly into this pattern. Helping a fellow addict with a syringe was an expression of the almost universal subcultural code of "share what you have."[37] These sharing behaviors functioned not only to satisfy individual craving, but also to support the maintenance of the network through the expression of community solidarity and the instrument of economic exchange.[35] In the AIDS era, needle sharing no longer serves this purpose. Rather, it has been transformed into a threat to the individual drug user, the friendship groups and networks, and the drug subculture as a whole. As with most cultural shifts, the process is gradual and never complete. Residues of the traditional code still remain and can be observed in emotional appeals and convenient lapses in newly acquired knowledge.

In conclusion, our findings suggest that needle sharing often is the outcome of structurally or situationally determined social interaction. Knowledge alone is not enough to counter the pressure of social interaction and drug craving. In these stressful situations, if clean syringes are not available, the strength of addiction will ultimately lead IDUs to unsafe injection practices. While easy access and a sufficient supply of clean syringes are effective in reducing unsafe practices, as van den Hoek et al. conclude,[9] they are not enough. They recommend intensive counseling in future preventive education efforts. Our findings support their suggestion by identifying a number of factors that determine needle sharing. These factors should be addressed in counseling that focuses on the practical skills of safe drug use. Furthermore, our results indicate that changes in the social environment may be more important than changes in individual risk behaviors. Prevention efforts may be made more effective by mobilizing social resources directed at preventing risk situations. IDUs and their networks should have a prominent role in such approaches, an idea that is getting more attention.[38–40] In Rotterdam our findings have shown that outreach programs working with IDUs to reinforce positive protective factors such as rules of safe use, while also distributing syringes to unknown IDUs via known ones can be effective in changing the environment.[20] Utilizing the knowledge of drug users and their information and exchange networks to promote risk reduction through peer education and peer support might offer more perspective on a lasting behavior change than any other prevention effort. □

Acknowledgments

APPENDIX[16]

The observational protocol used in this investigation provides an instrument to guide field research of heroin routes of administration in naturalistic settings. For theoretical purposes, we have termed the routes of administration for heroin observed in naturalistic settings as heroin rituals. The concept of ritual has been used in previous studies of drug use.[41] Our operational definition of ritual has been adopted from M. H. Agar[42]: "For an event to be a ritual event, it must prescribe a sequence of psychomotor acts . . . [and] the prescribed psychomotor sequence must be invested with a special meaning for the person performing that sequence." (p. 141). The instrument is partitioned across two dimensions. The first dimension, heroin rituals, consists of two categories; spuiten (injecting) and chinezen ("chasing the dragon," smoking). The second dimension refers to observational cues, classified as exogenous and endogenous. Exogenous cues index external ecological events that correspond to the "prescribed psychomotor sequence." In addition, participant background characteristics, paraphernalia, and environmental features partly compose this category. Endogenous cues index internal psychosocial events that correspond to the "special meanings" of the rituals. Internal experience is routinely expressed and displayed through language or gesture thereby available for direct observation in naturalistic settings.

Table A provides an overview of endogenous and exogenous cues cross-classified by the rituals. The table has the character of "fuzzy (sub)sets" with overlap of the formal items assigned to its four cells. In addition, this classification may not be exhaustive: future research may add new dimensions, categories, or items to the instrument.

Socioeconomic Status and Electrolyte Intake in Black Adults: The Pitt County Study

ABSTRACT

Background. Although the inverse association between socioeconomic status (SES) and blood pressure has often been observed, little is known about the relationship between SES and dietary risk factors for elevated blood pressure. Therefore, this study described the distribution of dietary intakes of sodium, potassium, and calcium and examined the association between electrolyte intake and SES among 1784 Black men and women aged 25 to 50 residing in eastern North Carolina.

Methods. Household interviews were conducted in 1988 to obtain information on psychosocial and dietary correlates of blood pressure. Electrolyte intake (mg/day) was assessed using a food frequency questionnaire adapted to reflect regional and ethnic food preferences. SES was categorized into three levels defined by the participant's educational level and occupation.

Results. After adjustment for age and energy intake, potassium and calcium intake increased with increasing SES for both sexes. Sodium intake was high for all groups and did not vary markedly with SES, but sodium to potassium and sodium to calcium ratios decreased with increasing SES. In addition, high SES individuals were more likely to believe that diet affects risk for disease and to report less salt use at the table and less current sodium consumption than in the past.

Conclusion. These data indicate that nutritional beliefs as well as the consumption of electrolytes are associated with SES in Black adults. (*Am J Public Health.* 1991;81:1608–1612.)

Introduction

As noted in several recent reviews,[1–3] socioeconomic status (SES) is inversely associated with mean blood pressure and the prevalence of hypertension. This inverse association has been observed among Blacks in the initial screening of the Hypertension Detection and Follow-up Program[4] and in a number of smaller, geographically dispersed community studies.[5–9] It is not yet clear what combination of biological, psychosocial, or environmental factors contributes to this relationship. Diet may be among the important environmental factors that influence the inverse relationship between SES and blood pressure.

The objectives of this report are to describe the distribution of dietary intakes of sodium, potassium, and calcium among Black men and women and to determine whether intake of these nutrients varies by SES. This report is part of the Pitt County Study,[10] which was designed to investigate psychosocial and dietary influences on the development of hypertension in young and early middle-aged Black adults residing in an eastern North Carolina community. This community is part of a larger area within the southeastern United States known to have high mortality from stroke and other hypertension-related disorders.[11]

A variety of nutritional factors, including intake of sodium, potassium, and calcium, have been associated with blood pressure level,[12–15] although intracommunity comparisons[16] are, in general, less likely to demonstrate significant effects than studies that examine diverse, multicountry experiences.[17,18] While most studies have not explicitly investigated differences in electrolyte intake by SES, variations in food consumption patterns or macronutrient intake by educational level and income have been reported.[19–23] Increased incomes are associated with greater consumption of meats, fruits and vegetables, and dairy products.[20,23] This is consistent with data from the Second National Health and Nutrition Examination Survey (NHANES II), which indicated that young adults below the poverty level consumed less potassium and calcium than those above the poverty level.[24] Sodium intake per 1000 calories did not differ by poverty status.[24]

The nutrient intake–economic status relationships investigated in these national surveys[23–26] and community-based populations[19] were not consistently stratified by race. However, large sample surveys of nutritional status and dietary behavior in the United States have shown lower

intakes of potassium, calcium, and magnesium in Blacks compared to Whites. Differences in calcium intake between Blacks and Whites may be due to a higher overall prevalence of lactase deficiency among Blacks in the United States.[27] In addition, Langford et al.[28] reviewed the diet–blood pressure relationship and concluded that the lower dietary intake of potassium and possibly calcium among US Blacks may be a major factor in explaining their well-known excess risk for hypertension.[1] Little is known about whether these nutritional determinants of blood pressure vary by SES among Blacks. This report is intended to help clarify the latter issue and, in doing so, facilitate more careful planning of dietary interventions to reduce risk for hypertension in US Blacks.

> High school	SES2 (n = 63)	SES2 (n = 117)	SES3 (n = 316)

Methods

Study Population

The study population is composed of a community-based sample of 25- to 50-year-old Black men and women residing in Pitt County, NC, in 1988. The sampling design identified housing units through an area probability sample. Area segments of housing units were selected with probabilities proportional to the expected number of Blacks residing in each area. All age-eligible men and women within selected housing units were invited to participate in the study. A major sampling objective was to obtain an economically heterogeneous sample. Eighty percent of the eligible sample of 2225, or 1784 adults, agreed to be interviewed.

Variables

Information concerning each participant's education, occupation, and other health and psychosocial characteristics was obtained from a personal interview conducted in the home. Physical measurements included blood pressure, height, weight, and the circumference of the waist and hips. SES was defined by a composite index based on the participant's educational level and most recent occupation. A composite index was created because previous research in a neighboring county indicated that education alone was not an adequate measure of overall economic resources.[29] The number of years of formal education completed was divided into three categories: less than high school graduate, high school graduate, and greater than high school. Using Hollingshead rankings of job prestige,[30] occupation was grouped into unskilled, semiskilled, and skilled/white collar categories. Three levels of SES were created from the cross-classification of education and occupation categories (Table 1).

Dietary information was collected via an interviewer-administered food frequency questionnaire adapted from a standardized instrument developed by Block et al.[31] Dietary assessment focused on the portion size and the frequency with which certain foods were consumed during the previous year. The food list, portion size distributions, and nutrient composition values were derived from Block's standardized instrument.[31] The instrument was modified somewhat to reflect regional and ethnic food choices known to characterize southern Black populations.

In reliability studies, the correlation between repeated administrations of Block's standardized instrument[31] was 0.70 for each nutrient.[32,33] The validity of the standardized instrument was also judged to be adequate with nutrient correlations ranging from 0.5 to 0.7 when food frequency dietary data were compared to three 4-day food records.[33,34]

Food frequency data were converted to nutrients consumed per day (in mg) for each individual.[31] In addition to calculated values of energy, potassium, and calcium, two estimates of sodium intake were used. The first measure included only the sodium consumed in food. The second measure, enhanced sodium, included both food sodium and an estimate of discretionary table salt use. Table salt use was estimated as 0%, 15%, or 30%, respectively, of the individual's food sodium if they said they either rarely/never, sometimes, or often/always added salt to their food. Sodium ratios were also calculated. Individuals with missing data (n = 104) were excluded from the analysis.

Questions concerning other factors that may influence food choices and attitudes that reflect knowledge of diet and health principles included the number of times in a typical week that the participant ate out, the change in use of salt during the last 5 to 10 years (more, same, less), and perceptions about whether diet affects risk for disease.

Statistical Analysis

The relationship between nutrient intake and SES was assessed by estimating nutrient intake means within each socioeconomic status category by weighted covariate analysis[35] using a multiple linear regression model. Two indicator variables were used to categorize high and medium SES with low SES as the referent group. Men and women were analyzed separately because of the expected greater caloric intake among men. Weighted analyses were performed to take into account the sampling strategy as well as nonresponse. The multivariable analyses of the relation between SES and electrolytes also included age and total caloric intake.[36] Levels of other determinants of consumption and nutritional attitudes were also characterized by strata of socioeconomic status.

Results

Little difference was noted in mean age, waist-to-hip ratio (WHR), and energy intake by level of SES among men (Table 2). Body mass index (BMI) was higher among men with high SES than low SES. Lower SES women were older than those in the other groups. BMI, WHR, and energy intake decreased with increasing SES among women, possibly because of the differences in age among the groups. As expected, the mean energy intakes of men exceeded those of women.

Table 3 shows that sample mean intakes of sodium and enhanced sodium for men and women were near or above the upper limit of the "estimated safe and ad-

equate daily dietary intakes" levels recommended as part of the 1980 Recommended Dietary Allowances (RDAs).[37] In addition, mean potassium was in the low range of recommended intake, particularly when considering the high general sodium intake and the fact that mean calcium intake fell below the RDA.

After adjusting for differences in age and energy intake among the SES groups, there was no consistent association between SES and sodium intake as measured by either food sodium or enhanced sodium (Table 4). Potassium and calcium intake increased with increasing SES for both men and women, with significantly ($P < .05$) higher intakes in the middle and high SES groups compared with the low SES group. Sodium to potassium and sodium to calcium ratios also decreased with increasing SES for both sexes. Similar results were found for the ratios when using enhanced sodium as the measure of sodium intake.

The distribution of potential determinants of nutrient consumption by level of SES are summarized in Table 5. Low SES respondents were more likely to live in large households (>5 persons). As expected, the proportion of men and women eating meals outside the home increased with increasing SES. For both sexes, those in the higher SES groups were more likely to agree with the statement that diet affects disease risk.

Men and women in the low SES group were more likely to report a high level of table salt use than those with higher SES. Men were more likely than women to salt food at the table. Both men and women in the low SES group were less likely to report a decrease in sodium intake from the previous 5 to 10 years. Interestingly, low SES men were less likely than middle and high SES men to perceive their salt intake as high. This last finding was not observed for women.

Discussion

Based on the 1980 RDA recommendations,[37] the distribution of electrolytes among Black adults in the Pitt County Study indicates lower than desirable calcium and potassium intakes and higher than desirable sodium intakes. Male study participants had a higher mean sodium intake and lower calcium and potassium intakes than 25- to 54-year-old Black and White men in NHANES II, which assessed dietary intake by 24-hour recall.[24] Sodium intake was also higher among women participants; however, calcium

and potassium intakes were similar. Sodium and potassium intakes in the Pitt County Study population were greater than those reported for Black men and women in Evans County in 1961.[38] A variety of factors may account for differences among these population studies, including secular trends, variation in dietary assessment instruments, and regional differences in food consumption.

Within the Pitt County Study population, Black men and women with high SES consumed more potassium and calcium and had lower sodium to potassium and sodium to calcium ratios than did those with low SES. These SES differences in electrolyte intake are consistent with the well-known inverse association between SES and hypertension.[4] However, the small magnitude of the differences in dietary intake across the SES categories (5% to 10%) in this study population is also consistent with literature reporting limited variation in dietary intake within populations compared to differences observed between populations.[16] Potential problems in the assessment of dietary intake include inflated variance estimates due to greater intra- vs interindividual variability. This could lead to an underestimation of the statistical significance of the differences among SES groups.[39]

Reasons that dietary intakes vary by SES are complex and involve many social and cultural processes. Not only do income, purchasing power, and access to food differ across SES, but access to and use of nutritional information probably differs by educational level. In addition, culture exerts a major influence on the selection, consumption, and use of the available food supply.[19] In this study, persons with high SES were more likely to believe that diet affects disease, to report less sodium consumption than in the past and less use of salt at the table. Approximately 70% of the study population did not consider their salt intake to be high. Given the overall high sodium consumption in this population, such a perception may warrant special attention in any community-based nutrition education program.

Large household size and the consumption of calories away from home have also been related to the intake of less healthy diets.[40,41] Compared to those with high SES, individuals with low SES were more likely to live in larger households but were less likely to consume foods away from home. The contrasting relations that household size (inverse) and the number of times respondents eat out per week (direct) have with SES may help explain the lack of variation in sodium intake across the groups.

TABLE 5—Percentage of Participants with Characteristics Affecting Food Consumption, by Sex and Socioeconomic Status (SES): Pitt County, NC, 1988

Characteristics	SES1	SES2	SES3
Men			
Household size (% >5)	20.2	11.4	8.7
Number of times eat out per week			
0	29.3	18.5	12.8
1	29.7	22.5	26.2
>1	41.0	58.3	60.0
Believe diet affects disease risk	77.3	91.2	91.8
Use tablet salt often/always	35.6	28.6	27.3
Consume less salt compared to 5–10 years ago	30.7	49.6	54.6
Perceive salt intake as high	23.1	28.8	32.0
Women			
Household size (% >5)	23.0	13.3	8.8
Number of times eat out per week			
0	40.3	23.3	14.2
1	33.2	34.4	22.5
>1	26.4	42.3	63.3
Believe diet affects disease risk	82.3	89.7	93.4
Use table salt often/always	23.5	21.0	19.2
Consume less salt compared to 5–10 years ago	45.2	52.7	52.2
Perceive salt intake as high	30.9	32.0	32.9

Note. SES1 = low; SES2 = middle; SES3 = high.

In conclusion, the differences in electrolyte intake by socioeconomic status observed in this population are consistent with the frequently reported inverse association between SES and hypertension. In this study population, a large percentage of individuals believed that diet influences risk for disease, but a much smaller percentage consumed the recommended level of these nutrients, reported reducing their salt intake over time, or considered their current salt intake to be too high. Therefore, health promotion efforts that target dietary behaviors in this and similar communities may need to develop population-based strategies to change food consumption patterns in the community as a whole. This will require an understanding of the social and cultural norms that sustain certain dietary behaviors at the individual level as well as an understanding of how local economic factors influence dietary options. Public health strategies that more effectively educate high-risk populations about the role of diet in cardiovascular diseases are clearly warranted. □

Representativeness of Deaths Identified through the Injury-at-Work Item on the Death Certificate: Implications for Surveillance

Julie Russell, PhD, MPH, and Carol Conroy, PhD, MPH

ABSTRACT

Background. This research investigated the accuracy of the injury-at-work item on the death certificate for surveillance of occupational injury deaths in Oklahoma during 1985 and 1986.

Methods. Representativeness of occupational injury deaths identified by death certificates was assessed by comparing these deaths with all occupational injury deaths identified through death certificates, workers' compensation reports, medical examiner reports, and OSHA records for categories of occupation, industry, and external causes of death.

Results. Certain external causes of death (e.g., motor vehicle traffic deaths) and certain occupations (e.g., farming) and industries (agriculture and services) are more often underidentified through death certificates.

Conclusions. The findings of this study support Baker's observation that no single data source contains all deaths or all the data elements necessary to describe occupational injury deaths. Data sources may be combined to improve representativeness through more complete case ascertainment. (*Am J Public Health.* 1991;81:1613–1618)

Introduction

Injury is the leading cause of death for persons under the age of 45, accounting for more years of potential life lost than heart disease and cancer combined.[1] Occupational injuries are an important subset of the larger injury problem and are estimated to account for one sixth of all fatal injuries to persons between the ages of 17 and 64.[2] Several private and federal agencies independently estimate the number of occupational injury deaths each year; however, there is currently no agreed-upon method for making such estimates.[3–7] For this reason, the annual number of occupational injury deaths differs widely between reporting sources. For example, the following widely discrepant estimates were made for the number of occupational injury deaths occurring in 1985: Bureau of Labor Statistics, 3750; National Institute for Occupational Safety and Health (NIOSH), 6385; and National Safety Council, 11 170.[3,5,6]

Several states and countries have used death certificates to describe occupational injury deaths.[2,3,8,9–28] They have also been used alone and in conjunction with other sources to study fatal injuries to farmers[22–24] and truck drivers[29] and homicides and suicides in the workplace.[14,25,26] The Division of Safety Research at NIOSH uses death certificates for surveillance of occupational injury deaths.[3]

The only variable on the death certificate used by NIOSH to define work relatedness is the injury-at-work item. However, the National Center for Health Statistics (NCHS) does not include this item in its vital statistics mortality tapes, there is no national guideline for its completion, and different states may define injury at work differently.

Table 1 summarizes the results of several state studies comparing case ascertainment using various data sources. These studies demonstrate that death certificates identify between 57% and 88% of occupational injury deaths. The literature indicates that occupational injury deaths are underreported using death certificates and that certain industries, occupations, external causes of death, and gender or race groups may consistently be underrepresented. For example, deaths that occur in occupations involving substantial amounts of driving of motor vehicles on public roads are often not identified as occupational fatalities.[8,29–31]

While surveillance systems often rely on sources that do not identify every occurrence of the condition under study,[32–35] the cases that are captured must be representative of the population of cases. If missing cases are distributed in occupation and industry groups similarly to cases in the surveillance system, there may be no bias in conclusions based on these data; however, if the cases missed are systematically different from those identified, then their exclusion could bias results, causing public health resources to be misdirected. Therefore, the representativeness of deaths identified by review of the injury-at-work item on death certificates is

At the time of this study, the authors were with the National Institute for Occupational Safety and Health, Division of Safety Research, Morgantown, WVa. TABLE 1—Percentage of Work-Related Fatal Injuries Identified from Various Data Sources, Selected Studies, United States, 1976–1987

Author, Date	State, Year(s)	Data Sources	Death Certificates Only	
			All Deaths (%)	Motor Vehicle Deaths (%)
Karlson, 1978[29]	Wisconsin, 1976	DC, WC	76	60
Baker,[a] 1982[31]	Maryland, 1978	DC, WC, ME, OSHA	67	
Roberts, 1983[9]	Michigan, 1980	DC, SIC	79	56
Paulson, 1986[30]	Colorado, 1982–1984	DC, WC, OSHA, MSHA	86	67
Robinson,[b] 1988[27]	Allegheny County, Pa, 1979–1982	DC, ME	57	
Friedman, 1989[28]	Massachusetts, 1987	DC, WC, OSHA, SIC	88	73

Note. DC = death certificates; ME = medical examiner reports; WC = workers' compensation reports, OSHA = Occupational Safety and Health Administration fatality/catastrophe reports; SIC = State Industrial Commission reports; MSHA = Mine Safety and Health Administration.
[a]Baker's study did not report the exact number of motor vehicle deaths.
[b]Robinson's study excluded motor vehicle injury deaths.

an important issue. This study was undertaken to evaluate the representativeness of deaths identified through death certificates alone for one vital statistics reporting unit (Oklahoma).

Methods

The study population consisted of all (resident and nonresident) workers who were fatally injured while working in Oklahoma during calendar years 1985 and 1986. Most of the analysis is restricted to males because injuries to females were too few to statistically analyze, although a brief description of these deaths is included in the results.

Work-related injury deaths were identified from four primary data sources: death certificates, Occupational Safety and Health Administration (OSHA) fatality/catastrophe reports, workers' compensation reports, and medical examiner reports. Two secondary data sources, workers' compensation court records and police accident reports, were used to confirm work relatedness when it could not be determined from the primary data sources. The working population was estimated from the Bureau of Labor Statistics Geographic Profiles of Employment and Unemployment for 1985 and 1986.[36,37]

An injury death was defined as an intentional or unintentional death resulting from an injury that can be classified by International Classification of Diseases (9th revision; ICD-9) external cause of death codes ranging from E800 to E999.[38] Work related was defined as including full-time or part-time workers as well as unpaid family members who are engaged in work activities in a work environment (e.g., family farms or other family businesses) at the time of their death.[2,39]

Death certificates on which the injury-at-work item was marked "yes" were acquired from the State Vital Statistics Office, as well as death certificates for work-related deaths that were identified from other sources and were not marked "yes" for injury at work.

Copies of the OSHA fatality/catastrophe reports for 1985 and 1986 were obtained from the state OSHA office. These reports are completed by OSHA within 48 hours of a death, the time in which employers are required to report a death to OSHA. Those regulated by other federal safety and health laws, government employers, and domestic workers are excluded from reporting requirements.

A listing for all filed workers' compensation death claims for 1985 and 1986 in Oklahoma was obtained from the State Workers' Compensation Court. These claims do not include self-employed individuals and government and domestic workers who are not eligible for workers' compensation benefits.

In most states, as in Oklahoma, medical examiners or coroners have jurisdiction over all occupational injury deaths.[40] Hand searching of medical examiners' records was required to identify occupational injury deaths in Oklahoma. Records of deaths were then matched visually by agreement of location of death, sex, external cause of death, date of birth, and name.

Demographic and external cause of death data were abstracted from death certificates. Results for the death certificate (DC) group were classified by "usual" occupation/industry, since only usual occupation/industry is reported on the death certificate. This represents the job that was worked for the longest period of time. The comparison group, all deaths (AD), was classified by the most current occupation/industry information that could be derived from any of the data sources. When workers' compensation and OSHA records were available, they were used as the primary sources of current occupation/industry information. When these reports were not available, the medical examiner reports and death certificates were studied in detail to determine whether the "usual" occupation/industry reported on the death certificate was the same as the current occupation/industry. The occupation/industry reported on the death certificate was determined to not be current when it was not consistent with the location and external cause of death. For example, a death certificate may indicate an occupation/industry of student/school, while the injury description on the death certificate and the medical examiner report indicate that the death occurred from a fall at a grain elevator while the victim was working. In this case, there is clear evidence that the "usual" occupation/industry information does not reflect the current occupation/industry.

Annual average rates were calculated by dividing the number of deaths for an occupation or industry group by the working population (i.e., the number of people employed in 1985 and 1986 in each occupation or industry group). Rate ratios were used to compare the pooled data rate and the death certificate–based rate. Rate ratios were calculated for occupation and industry for AD and DC.

Results

Three hundred twenty-nine occupational injury deaths (299 males, 30 females) were identified during 1985 and 1986, making the annual average death rate 11.3 per 100 000 workers (2.3 for females, 18.7 for males). Twenty-eight of the 30 (93%) female occupational injury deaths were identified by death certificates. Seventy percent of the female deaths occurred in two workplace disasters: an explosion in a fireworks factory and a mass homicide at a post office. These events were highly publicized, possibly increasing the chances of the deaths being recorded as work related. Seventy-three percent of the female deaths were in the manufacturing and public administration industries. Sixty-seven percent of female deaths were in the laborers and helpers and administrative support occupations. There were no female deaths in the four highest risk industries of transportation, communications, and public utilities; construction; agriculture, forestry, and fishing; and mining. Females were excluded from further analysis because of the small numbers of deaths and the two clusters of female deaths.

Of the 299 male deaths, 82% (244) were identified through medical examiner reports, 72% (215) through death certificates, 57% (169) through workers' compensation reports, and 24% (72) through OSHA fatality/catastrophe reports (Figure 1). Cases identified through OSHA fatality/catastrophe reports were not included in Figure 1 because only one additional case was reported to OSHA and not identified in the other three data sources.

There was 86% agreement between usual and current industry for the two-digit Standard Industrial Classification (SIC) and 81% agreement between usual and current occupation when 11 broad occupation categories were used.[41]

When characteristics of deaths were compared for AD and DC, the distributions for age, race, and place of injury were generally similar. The distributions for external cause, shown in Table 2, are similar except for a discrepancy in the identification of traffic deaths (ICD-9 E810.0 to E819.9) between AD and DC. Only 60% (44/73) of these deaths were identified through death certificates (Figure 2).

The distribution of intentional injuries was similar between AD and DC except for suicides that occurred at work, with only 14% (2/14) of suicides being identified through death certificates. Since suicides account for only 5% of AD, the proportion in relation to all occupational injury deaths did not change.

Rate ratios are used to compare industry death rates for AD and DC in Table 3. Rate ratios are 1.5 or greater for four industries: finance, insurance, and real estate; agriculture, forestry, and fishing;

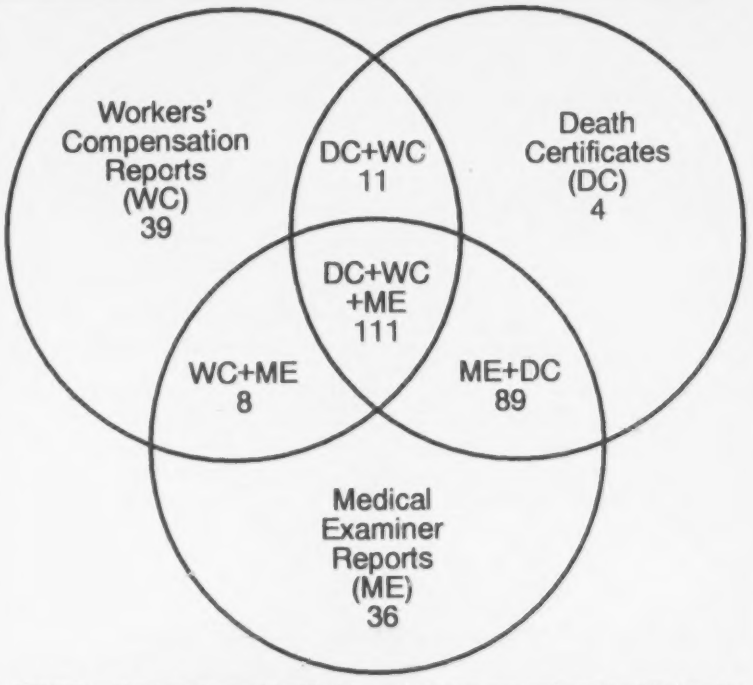

FIGURE 1—Number of cases identified, by each data source, male work-related deaths, Oklahoma, 1985–1986.

TABLE 2—External Causes of Death by Ascertainment Source: Male Work-Related Deaths, Oklahoma, 1985–1986

ICD-9 E Code	DC (frequency)	AD[a] (frequency)	DC/AD (%)
Traffic (E810–E819)	44	73	60

Services (SIC 700–899)	6.4	14.7	2.3
Trade (SIC 500–599)	6.0	11.3	1.9
Finance, Insurance, Real Estate (SIC 600–679)	2.0	7.8	3.9
Overall rate	15.4	21.4	1.4

Note. Industry groups are defined by the Office of Management and Budget, Standard Industrial Classification (SIC), 1987.
[a]Includes cases identified by death certificates, medical examiner reports, Occupational Safety and Health Administration fatality/catastrophe reports, and workers' compensation reports.

services; and mining. Fifty-one percent of the deaths not identified through death certificates occurred in three industries (mining, agriculture, and services).

Occupation death rates are compared for AD and DC in Table 4. Rate ratios were 1.5 or greater for five occupation categories: helpers and laborers; farming occupations; executive, administrative, and managerial occupations; technical and related support; and machine operators, assemblers, and inspectors. Fifty-seven percent of the deaths missed by death certificates were in the four highest risk occupations (helpers and laborers; transportation and material moving operatives; farming occupations; and precision production, crafts, and repairers).

In Figure 3 the distributions for death rates by industry based on the pooled data are compared with the death rates based on death certificates only. The distributions have the same shape; however, the pooled data show higher death rates per 100 000 workers and substantially higher rates for mining and agriculture.

Discussion

Death certificates are shown in this research to identify 72% of the fatal occupational injuries occurring to males and 93% for females in Oklahoma during 1985 and 1986. Previous studies show that death certificates alone underestimate the magnitude of the occupational injury problem in the United States by 24% to 33%.[2,30] Although the results of this study (underestimation by 28% for males) cannot be directly generalized to the United States, they agree with results of previous studies in Colorado,[30] Maryland,[2] and Wisconsin[29] on the basis of case ascertainment using death certificates.

Certain external causes of injuries (traffic deaths) and certain industries (mining, agriculture, and services) and occupations (laborers and helpers; farmers; transportation and material moving operatives; and precision production, crafts, and repairers) were less often identified through the injury-at-work item on the death certificate than others and point to areas where estimates of death rates based on death certificates should be interpreted with caution.

Death certificates have been shown to accurately identify broad categories of occupation and industry that are at highest risk of occupational injury death when NIOSH's death certificate database was compared with the Bureau of Labor Statistics annual survey.[19] While this broad agreement is useful to draw attention to the problem and to estimate its overall magnitude, more targeted surveillance for specific external causes or occupation/industry groups is necessary to plan and implement intervention strategies. This targeted surveillance may not be possible through death certificates.

The use of death certificate data for surveillance of occupational injury deaths hinges on the assumption that usual occupation and industry, as reported on the

death certificate, serves as an acceptable proxy for the occupation/industry the person was engaged in at the time of death (current occupation and industry). This assumption appears to be valid for analysis of broad categories of industry and occupation. However, lack of current occupation and industry information is a serious limitation to any study based on death certificate data alone and intended to target interventions in a defined population (e.g., a county or state), since the occupational and industry groups at highest risk are the least likely to be identified through death certificates.

Occupation/industry is a crude method to measure the exposure of workers to harmful energy exchanges at work; therefore, accurate information on the current occupation/industry of the decedent at the time of death is critical to planning and implementation of prevention programs. Two recent studies show that the agreement for usual industry and current industry ranges from 68% to 72% and the agreement for usual occupation and current occupation ranges from 70% to 78% for the identified occupational injury deaths.[30,42] Goodman[22] found that 59% of people killed on farms in Georgia during 1971 to 1981 did not have the occupation of farmer noted on their death certificate. Furthermore, a group of potentially high-risk workers—students—are often not classified by the industry or occupation they were working in at the time of death. National death certificate data from 1980 to 1985 reveal that 16% of the deaths of persons under the age of 21 were noted with industry as student on the death certificate. The proper classification of this group of workers by the occupation they were engaged in at the time of fatal injury is important to the surveillance and prevention of injury deaths to young workers.

National surveillance of occupational injury deaths is needed to provide national estimates of fatal occupational injuries by occupation, industry, and external cause of death. These estimates can help prioritize research programs and target specific occupations, industries, and causes of death for intervention programs. Because death certificates are the only source of data that potentially includes all workers, every effort should be made to improve identification of occupational injury deaths on death certificates and improve the quality of the occupation and industry data, in addition to developing systems to link data sources for national surveillance. The findings of this study support the observation that no single data source contains all of the data elements needed to describe occupational injury deaths and plan prevention strategies.[2,43]

Measures to improve representativeness as well as ascertainment of occupational deaths through the use of death certificates include the following:

1. A clear definition of when a person is considered "at work" is needed for recording work-related injuries that can be used in workers' compensation reports and by coroners, medical examiners, and researchers. There is also a need for a definition of a work-related injury. For example, a woman who is killed by her husband while she is working suffered an "injury at work"; however, many death certifiers may be reluctant to call the death work related.

2. Certain classes of ICD-9 external

TABLE 4—Annual Average Death Rates per 100 000 Workers by Occupational Group and Ascertainment Source: Male Work-Related Deaths, Oklahoma, 1985–1986

Occupational Group	Usual Occupation Death Certificate Rate	Current Occupation All Death[a] Rate	Rate Ratio
Helpers and Laborers (OCS 863–889)	36.0	57.2	1.6
Transportation and Material Moving (OCS 803–859)	36.6	46.4	1.3
Farming (OCS 473–499)	15.3	31.6	2.1
Precision Product, Craft, Repair (OCS 503–699)	11.7	15.4	1.3
Services (OCS 403–469)	10.0	13.7	1.4
Sales (OCS 243–285)	6.6	9.3	1.4
Executive, Administrative, Managerial (OCS 003–037)	3.3	7.6	2.3
Technical Support (OCS 203–235)	5.5	12.9	2.3
Professional Specialty (OCS 043–199)	5.4	7.8	1.4
Administrative Support (OCS 303–389)	11.7	10.6	1.1
Machine Operators, Assemblers, Inspectors (OCS 703–799)	3.0	6.0	2.0
Overall rate	13.5[b]	18.7[c]	1.4

Note. Occupational groups are defined by the 1980 Bureau of Census Occupation Coding System (OCS).
[a]Includes cases identified by death certificates, medical examiner reports, Occupational Safety and Health Administration fatality/catastrophe reports, and workers' compensation reports.
[b]Twenty-four cases identified by death certificates had occupational information missing or not classified.
[c]Fifteen cases in the pooled data had occupational information missing or not classified.

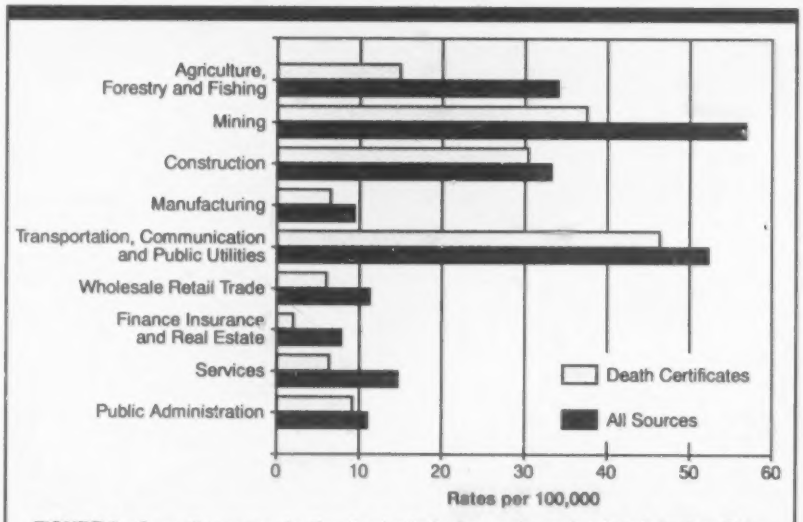

FIGURE 3—Annual average death rates by industry, male work-related deaths, Oklahoma, 1985–1986.

cause of death codes that are usually occupational (e.g., ICD-9 E919) should be identified, and state vital statistics offices should be asked to query death certifiers to confirm work relatedness when the injury at work item is marked "no" or is blank.

3. Current industry and occupation, in addition to "usual" occupation and industry, should be included on the US standard death certificate.

4. Responsibility for identifying and automating death certificates for injury-at-work deaths should be transferred to NCHS, so there will be uniform recording, quality control procedures, and timely dissemination of data.

5. Death certificates should be linked with medical examiner/coroner records in states that have a centralized and automated medical examiner/coroner system to make toxicology screening data available as well as detailed information on the nature and severity of injuries.

6. Death certificates should be linked with workers' compensation first reports of injury to improve case ascertainment, especially of occupational motor vehicle injury deaths. □

Acknowledgments

This research was supported by the National Institute for Occupational Safety and Health, Division of Safety Research.

Results of this research were presented, in part, at the 116th Annual Meeting of the American Public Health Association, in Boston, Mass., November 1988.

We are indebted to Drs. Greg Istre and Mark Roberts of the Oklahoma State Department of Health and to the Oklahoma chief medical examiner, Dr. Fred Jordan, and his staff. We also acknowledge the cooperation of the Oklahoma Workers' Compensation Court and the Oklahoma Occupational Safety and Health Administration, who provided records and helped make this research possible.

Occupational Health and Safety in Brazil

Howard Frumkin, MD, MPH, and Volney de M. Câmara, MD

ABSTRACT

Background. Brazil is the world's fifth largest and sixth most populous nation. Its economy is varied, with strong manufacturing, agriculture, mining, and service sectors. Therefore, a wide variety of workplace hazards confronts its work force. This paper describes Brazil's occupational safety and health regulatory scheme, workers' compensation system, plant-level practices, training, and data collection.

Methods. We reviewed and analyzed Brazilian regulatory legislation and government and non-governmental organization (NGO) activity in occupational safety and health, as well as the structure and function of the workers' compensation system. We also reviewed available data on injuries and diseases from major sources, including the now-defunct Instituto Nacional do Previdencia Social (INPS) and the workers' compensation scheme, Seguro de Acidente de Trabalho (SAT).

Results. The incidence of workplace injuries has decreased in recent years and is now reported to be about 5 per 100 workers per year. The case fatality rate has been constant at about 5 fatalities per 1000 injuries. Less than 6% of reported injuries are classified as "diseases." Brazil's rates are comparable to those of Mexico and Zimbabwe, and two to four times higher than in most industrialized countries.

Conclusions. Brazil has a high incidence of occupational injuries and diseases; these injuries and diseases are underreported; there is a large informal sector at special risk; and Brazil illustrates the disparity that exists in many countries between legislation on the books and legislation that is actually implemented. (*Am J Public Health.* 1991;81:1619–1624)

Background

History

Brazil is the world's fifth largest nation, with an area of 8.5 million km^2, and the sixth most populous, with approximately 150 million inhabitants.[1] It is a physically diverse nation, rich in natural resources. Until the 20th century, the economy depended principally on sugarcane, coffee, hardwood, and rubber production, and on gold and diamond mining. Because of fluctuating world markets for these products and dependence on a small number of export products at any time, Brazil's economy oscillated throughout the 19th century. During the 20th century, however, successive national governments have encouraged diversification. Industrialization has proceeded rapidly, and manufacturing now constitutes the largest portion of the gross domestic product. Tremendous economic growth has continued during most of the 20th century, especially during the 1960s and 1970s. However, serious economic and political problems persist, including marked income maldistribution, uncontrolled inflation, and one of the world's largest foreign debts.

Industry and Agriculture

The Brazilian economy includes well-developed mining, agriculture, manufacturing, and service sectors.

Rich mineral deposits support an extensive mining industry. There are major deposits of iron ore, bauxite, hematite, oil, and gas in many areas. Aluminum and manganese are mined in the Amazon region, chrome, magnesium, and quartz in Bahia, copper and lead in Bahia and Rio Grande do Sul; asbestos in Goias; and nickel in Goias and Minas Gerais. Brazil is self-sufficient in tin, zinc, and tungsten. Of particular interest is the gold found in the Amazonas region, which is mined by approximately 600 000 *garimpeiros* (gold-seekers) working outside the formal sector.[2] Mining employs about 4 million people nationally.[3]

Agricultural production has increased over recent decades as a result of increases in areas under cultivation, but the relative importance of agriculture in the nation's economy has declined with the growth of industry. Major crops include coffee (Brazil is the world's largest producer), soybeans, oranges, and sugarcane; the latter has increased in importance in recent years with use as a source of ethanol for fuel. Other crops include cassava, rice, cacao, and bananas. Brazil also has a sizable forestry industry, producing eucalyptus, pine, and a variety of hardwoods, and a significant fishery. Between 13 and 16 million people, slightly less than one third of the work force, work in the combined agriculture/forestry/fishing sector, representing a significant decline over recent decades.[2,4]

Brazil's manufacturing sector is a rapidly growing, vibrant part of the economy. Major products include steel, chemicals, petrochemicals, textiles, automobiles, pulp and paper, aircraft, electronics,

At the time of this study, Howard Frumkin was with the University of Pennsylvania School of Medicine. Volney de M. Câmara is with the Faculty of Medicine, Universidade Federal do Rio de Janeiro, Brazil. Both are affiliated with (INCLEN) the International Clinical Epidemiology Network.

[a]Depends upon fiber type.

and footwear. The petrochemical industry is Latin America's largest. The manufacturing sector now employs about 25% of the work force, and continues to expand.[3,4] Civil construction employs large numbers of workers. The service sector is the fastest growing part of Brazil's economy, and now employs more than one third of the work force.

The greatest concentration of industry in Brazil is in the Southeast, centered around the cities of São Paulo, Rio de Janeiro, and Belo Horizonte. About one fifth of the nation's industry is in the South, and a very small portion is in the North.

The Brazilian Work Force

About 45% of Brazil's population, nearly 70 million people, are considered economically active, of whom about 60 million are employed. This includes about 20% of children aged 10 to 14, representing a significant pool of child labor.[5]

Most Brazilian workers are employed in small workplaces.[6,7] However, since no official data are gathered on employment by enterprise size, this trend is difficult to quantify.

Women constitute about 35% of Brazil's work force. Female workers tend to have completed more schooling than male workers. Overall, however, women are relatively more concentrated than men in the service sector and less concentrated in manufacturing, mining, agriculture, and construction, and they earn lower wages than men.[8]

Occupational Safety and Health Practice

History

Awareness of workplace accidents grew in the early years of the 20th century, along with larger concerns about the wages and living conditions of workers. Several state-level initiatives during the first two decades of the century addressed the problem of workplace accidents. A national law that regulated workplace safety conditions (Law No. 3724) was promulgated in 1919 and altered in 1934. During the decades of rapid industrialization that followed World War II, the number of reported accidents and their economic burden increased dramatically. The national government took action in 1968 by issuing Ordinance 32, which defined requirements for safety and health initiatives at the workplace level. Since then, further regulations have been promulgated on the federal level and in some states.

Regulation of Workplace Conditions

The legal framework for occupational health regulation is complex, ranging from the federal constitution (newly issued in 1988) to long-standing Ministry of Labor ordinances. Most occupational health functions have been housed in the Ministry of Labor, but with the reorganization of the health sector in 1988 into the Unified Health System (Sistema Unico de Saúde, or SUS), some responsibility was shifted from the Ministry of Labor to SUS. The new constitution empowers SUS to act in protecting worker health (Article 205, Sections II, VIII) but generally does not define how this is to be done. No specific piece of legislation defines a standard-setting process. The constitution does empower the Federal government to conduct workplace inspections (Article 21, Section XXIV). It remains to be seen how regulation and workplace inspection will be conducted by SUS under the new arrangement.

For the present, occupational health regulation continues to be an activity of the Ministry of Labor, pursuant to the Consolidated Labor Law of 1943 (Decreto-Lei 5452). In addition to federal activity, state and municipal governments issue some laws and regulations of their own. The Ministry of Labor has generally based its regulations on threshold limit values (TLVs) issued by the American Conference of Governmental Industrial Hygienists (ACGIH).[9,10] Of interest, the exposure limits are based on a 48-hour workweek, rather than the 40-hour workweek assumed in US limits. (The longer workweek remains common in Brazil, although the new constitution limited the workweek to 44 hours.) A list of regulated substances appears in Table 1. Several observations may be made. First, despite the equivalence of many standards (adjusted for differing workweeks), Brazil permits far higher exposure to certain substances, either through more permissive standards or through the complete absence of standards. Second, Brazilian standards based on older ACGIH TLVs have not been updated apace with ACGIH updates. For example, Brazil's methylene chloride standard is based on an older ACGIH TLV that, in the United States, was lowered in 1988. Third, there is far more attention to long-term outcomes, especially cancer, in ACGIH recommendations than in Brazilian regulations. Several carcinogens, such as chromium compounds, are not regulated in Brazil, and others are regulated less stringently.

Although some stringent regulations are in place, the Ministry of Labor has maintained virtually no workplace inspection capacity, and little enforcement has occurred. If a violation is discovered, a labor justice may impose a fine, but the maximum fine prescribed by law is only 10 times the minimum wage for a month (Chapter 5 of Law 5242 of 1943).

Occupational Safety and Health Service Delivery

Ordinance 32 of 1968, which was updated in 1983, requires companies to establish an Internal Committee for the Prevention of Accidents (CIPA). Specific requirements for this committee are based on the risk level and on the number of employees.[11] The main objectives are the prevention of accidents and the monitoring of safety and health conditions in the plant. Although the committees must contain an equal number of labor and management representatives, the chairman is a management representative. Moreover, although Ordinance 32 protects CIPA labor representatives from discharge because of their committee activity, anecdotal evidence suggests that this protection is sometimes violated. These factors compromise the independence and effectiveness of the workplace committees.

In addition to workplace safety and health administration, professional staff requirements are defined by law. A 1972 ordinance (No. 3237) mandated specialized hygiene and occupational medicine services for enterprises according to the number of employees and risk level. For example, a high-risk firm with 1500 employees is required to maintain one occupational physician, one aide, one safety inspector, and one occupational engineer. The ordinance defines the occupational medical role broadly as including preemployment and periodic medical examinations, worker education, surveillance activity, etiologic study, and committee work at the plant level.

Workers' Compensation

The workers' compensation function was fully integrated into the nation's larger social welfare system in 1967 by Law 5316, which required all employers to insure their employees through what was then the National Institute for Social Welfare (Instituto Nacional do Previdencia Social, or INPS). Under the restructuring introduced by President Collor de Mello in 1990, the INPS was dissolved. All its social welfare functions, including workers' compensation, were transferred to the Ministry of Labor in the newly formed Instituto Nacional de Seguridade Social (INSS). Although some changes may occur, it is likely that the INSS compensation scheme will preserve many of the features it developed under INPS between 1967 and 1990.[5]

The workers' compensation scheme is called Seguro de Acidentes de Trabalho (SAT). In case of an occupational injury or disease, this scheme offers substantial benefits above ordinary medical coverage. These include medical costs, full wage replacement, compensatory payments for loss of function, rehabilitation costs, and death benefits.

The INSS is funded by equal contributions from employees and employers, each composing 10% of the payroll. Because INSS also acts as Brazil's workers' compensation insurance carrier, it collects extra funds to support this function. Payments are collected from employers according to each industry's risk profiie. Premiums range from 2.5% of the employees' salaries in high-risk enterprises to 0.4% in low-risk enterprises. Risk in this context is evaluated on the basis of lost time accidents (of more than 15 days), a point to which we return below.

When an occupational injury or illness occurs, the employer is required to report it to the INSS within 24 hours. The report automatically triggers SAT coverage, which pays for medical care. The employer continues to pay full wages for the first 15 days of lost time, at which point the SAT takes over with continued full wage replacement. If a company fails to report an injury or illness, claiming that it is not occupational, then a worker may take the case to labor court.

There are many failures of this system.[12] First, the SAT scheme includes only about 25% of the working population, since only about half of workers are covered by the INSS, and only half of those work for companies required to pay into SAT. Civil servants, physicians, and self-employed people, for example, would typically be covered by INSS but not by SAT. Rural workers, who constitute close to 30% of Brazil's work force, are also not covered by SAT. Moreover, companies have an incentive not to report injuries and illnesses, mostly a matter of public image rather than finances. This is especially true of injuries that result in less than 15 lost workdays, since the SAT offers wage replacement only after that interval. In addition, physicians often fail to diagnose occupational illnesses correctly, and workers often are unaware of procedures for submitting injury reports and gaining compensation. For all these reasons, the SAT fails to provide compensation to many workers who become injured or ill at work. The extent of this problem is unknown.

Of additional importance, SAT reports are the sole source of occupational injury and illness data in most of Brazil. Some states, such as Rio de Janeiro, require reporting of certain occupational conditions, but this is a variable and incomplete resource. Therefore, the failures of the workers' compensation system translate into failures of occupational health and safety data as well.

Labor Union Activity

Approximately 22% of Brazilian workers belong to labor unions.[13] The unions have been relatively inactive in occupational health and safety because of restrictions imposed by the military government until 1985 and because of more pressing economic concerns. However, some labor unions have recently increased their activity in the field, perhaps supported by growing awareness of environmental devastation in some parts of the country with consequent health costs. In 1979 the two labor union confederations, Central Unica de Trabalhadores (CUT) and Confederação Geral de Trabalhadores (CGT), formed the Interunion Department for the Study of Health and Work Environment (Departamento Intersindical de Estudos de Saude e dos Ambientes do Trabalho, or DIESAT). DIESAT advises local unions on safety and health problems, publishes a monthly newsletter, offers seminars, and participates in investigations. The increasing union activity has been evident at the state and national level. In 1980, for example, the "Sindicatos dos Trabalhadores Rurais de Campos-Rio de Janeiro" won a national prohibition of the use of organomercurial fungicides. In 1988, pressure by the keypunchers union, Associação dos Profissionais de Processamento de Dados (APPD), resulted in recognition by the state government of Rio de Janeiro of tenosynovitis of the fingers as a reportable occupational disease among keypunch operators.

Injury and Disease Reporting

In Brazil, workplace injuries are defined as "all events that happen during the practice of work directly or indirectly causing physical lesion, functional disturbance or illness, and resulting in death or

TABLE 2—Designated Causes of Occupational Diseases According to Decreto 79.037, December 1976

Arsenic
Asbestos

Silica dust
Tar, asphalt, paraffin, and related materials

loss of the capacity to work, whether total or partial, temporary or permanent."[14] These include injuries at work or while commuting, officially designated occupational diseases, and other diseases found to be work-related. The list of designated causes of occupational diseases (see Table 2) was set forth in December 1976 by Decreto 79.037. For some diseases, Decreto 79.037 specifies particular operations and techniques that are considered pathogenic. This may result in underrecognition of occupational disease; if an operation that causes disease was omitted by the ordinance or was introduced after the ordinance was written, it is not acknowledged as a cause of occupational disease.

The report of an injury is the responsibility of the employer. After the employer has been informed of the injury, the Ministry of Labor must be notified within 24 hours and given a description of the injury.[11] These data are tabulated, but very little further analysis is performed. There is no systematic effort to identify hazardous enterprises or to apply these data to enforcement or policy decisions.

One source of error in injury statistics derives from the fact that commuting injuries are notifiable. When a worker is injured over the weekend, he or she might report that injury as a commuting injury upon arriving at work Monday morning. This phenomenon is apparently common in some companies, although difficult to quantify. It may partially explain the peak in injuries seen on Mondays (data not shown).

Training

Medical and nursing curricula in Brazil vary in their occupational safety and health content. In major universities in Rio de Janeiro, São Paulo, and Minas Gerais, considerable time is devoted to occupational safety and health. For example, the medical curriculum at the Federal University of Rio de Janeiro includes 126 contact hours in occupational medicine during the third year. Other universities have considerably less instruction in occupational safety and health.

Specialty training in occupational safety and health was greatly promoted by the 1972 ordinance that requires occupational physicians, industrial hygienists, and occupational health nurses at plants. These functions were initially well salaried in a nation that suffers from professional unemployment, so large numbers of physicians and nurses sought certification. Within several years, universities responded to the increased demand by offering large numbers of training programs. The result was a large complement of occupational safety and health professionals by the late 1970s; over 20 000 occupational physicians were trained during that decade.[15] Presently, about 10 universities throughout the nation offer specialty training in occupational medicine, occupational nursing, and industrial hygiene. Certification in occupational medicine or nursing requires 360 hours of instruction over 1 year, usually taken as an evening course. Upon completion of the course, the Ministry of Labor certifies graduates, which qualifies them to fill the role defined by law. This function may be taken over by the Ministry of Education in coming years.

Available Data on Occupational Injuries and Diseases

The data in this report are derived from the population covered by the SAT scheme. Although the Ministry of Labor must be notified of all workplace injuries, only those injuries resulting in at least one lost workday are reported. In contrast, most other countries' data are based on 3-day lost work time injuries. The numerator data reported here were obtained from the INPS, and the denominator data were obtained from the Brazilian Institute for Geography and Statistics, or IBGE.[8] A foundation based in the Ministry of Labor, FUNDACENTRO, also publishes workplace injury reports in its bulletins, again based on INPS data.

Figure 1 shows the occupational injury incidence rate (including both occupational diseases and transit injuries) per 100 employees. Despite the deficiencies in reporting, the data indicate that Brazil has a high incidence of occupational injuries. This rate increased until 1972 and decreased thereafter. At least two explanations may be offered for the change: improving working conditions or less complete reporting of injuries.

In support of the first explanation, at least two developments may be cited. One is the legislation that mandated plant-level occupational health services. Second, increased training in occupational safety and health at the university level might have contributed to a decrease in workplace injuries.

In support of the second explanation, several observations are relevant. First, as noted above, most of the Brazilian working population is employed in small enterprises that were not required to establish Internal Committees and Occupational Health Services. Second, a major change in Brazil's insurance legislation occurred in 1975. Until then, the employer was required to pay a worker's salary on the day of a workplace injury, while the INPS assumed this role on the second day. After 1975, employers were required to pay the injured worker's salary until the 15th day after the injury. This change was a powerful incentive for companies not to report injuries. Unfortunately, the Ministry of Labor has not monitored companies' compliance in recording and notifying injuries, so the extent of underreporting is unknown.

Several other observations suggest that the reported data are underestimates. First, the SAT data cover only about 25% of the work force, excluding especially hazardous sectors such as agriculture. Second, the number of reported occupational diseases (which are included in injury data) is very low. Physicians in Brazil are still not familiar with the relationship between work and health,[12] and specialized diagnostic services such as toxicological laboratories are rare. Finally, the apparent decrease in occupational injury incidence did not correspond to a similar decrease in the occupational fatality rate. In Brazil, as in other developing countries, mortality records are usually more reliable than morbidity and other data. Figure 1 shows that the case fatality rate increased from 1970 through 1987. The likely explanation is that fatal injuries continued to be notified, while nonfatal injuries did not. Although international comparisons are

difficult, it appears from available data that Brazil's workplace fatality rate is significantly above that of other countries, as shown in Table 3.

Figure 2 shows the proportion of occupational diseases and transit injuries included in the total number of injuries. Reported cases of occupational disease have never exceeded 1% of the total, probably reflecting significant underreporting of disease. On the other hand, there has been an increasing trend in transit injuries, reflecting better reporting and/or increasing risk in a nation with increasingly congested and dangerous roads.

The rate of occupational disease notification in Brazil was estimated during a study of organomercury fungicide use by sugarcane workers in the district of Campos, State of Rio de Janeiro.[16] For the year 1980, 1456 occupational injuries were registered, including one occupational disease. In this same year, 30 sugarcane workers were submitted to a clinical and laboratory examination, which revealed 21 cases of mercury poisoning with blood levels of mercury as high as 0.25 ppm. None of the 21 affected workers was among the 1456 reported cases, suggesting widespread underreporting.

Conclusions

Several conclusions emerge from this review of occupational health and safety in Brazil. First, there is a high incidence of occupational injuries and diseases. This is common among developing countries, often to a worse degree than in developed nations. Brazil illustrates the tension that may exist between economic development and attention to health concerns. In nations with crushing foreign debts, like Brazil, the economic crisis may eclipse less immediate and pressing concerns such as occupational safety and health. Constituencies that might promote safety and health measures, such as labor unions and the health sector, are forced in this situation to direct their efforts to other issues. This tension exists in all developing nations, and may be expected to continue in the foreseeable future. It highlights the importance of greater attention to occupational health in Brazil, and of vigorous attempts to prevent injuries and illnesses.

Second, there is evidence of serious underreporting of occupational injuries and illnesses, worse with illnesses than with injuries. Among the most important reasons are the exclusion of a majority of the work force from the only systematic data collection system, reliance on employers for notification despite incentives against notifying, and underdiagnosis of occupational diseases by physicians. On the other hand, two factors may increase reporting relative to other nations: the inclusion of injuries that occur while commuting and the reporting of injuries that result in as little as one lost workday. In any case, more consistent, standardized injury and disease surveillance is clearly required.

A third conclusion relates to the informal sector of Brazil's economy. As is the case in many developing nations, a large portion of Brazil's work force is marginalized and excluded from services. Examples include the street vendors who are ubiquitous on the streets of major cities, agricultural workers, and the gold-seekers in the Amazon basin. These groups may be at special risk of occupational injury and disease, and special efforts must be made to extend surveillance and prevention programs to them.

Brazil also illustrates the disparity that may exist between legislation "on the books" and reality. It has a relatively complete set of laws that relate to occupational safety and health, but enforcement is erratic and generally absent. As a result, hazardous conditions persist in many workplaces. Similarly, although national legislation triggered training of a large number of occupational health professionals, especially physicians, this group has not had the impact on workplace conditions that might have been hoped. These observations suggest that vigorous action by regulators, labor unions, and professionals may be necessary to achieve real change.

TABLE 3—Occupational Fatality Rates in Several Countries

Country	Fatality Rate Per 1000 Employees
Zimbabwe	.217
Brazil	.220
Cuba	.102
Mexico	.240
United States	.068[a]
Japan	.025[a]
Spain	.127
Holland	.016
Poland	.109

Note. Mexico data are for 1986, Brazil and US data are for 1987, Zimbabwe data are for 1989, and all other countries' data are for 1988. *Source:* International Labour Office. *Year Book of Labour Statistics, 1989–90.* Geneva, Switzerland: ILO; 1990: Table 30.
[a]Rates for Japan and the United States are given as fatalities per 1 000 000 person hours worked. These rates were multiplied by 2.5 to convert to fatalities per 1000 persons.

An interesting and unusual feature of Brazil's occupational health landscape is the integration of almost all occupational health services into the health sector. Historically, the provision of social services has been tied to work. Almost 25 years ago, the workers' compensation function was integrated into the INPS, although

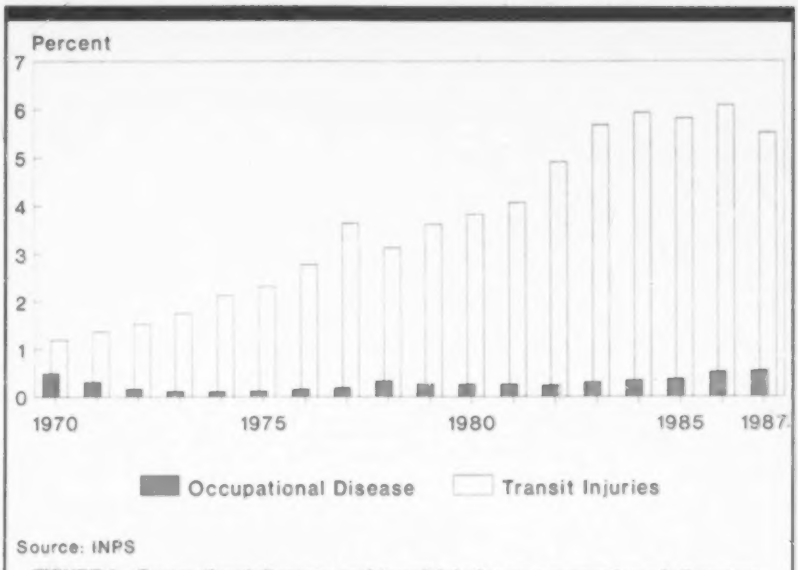

FIGURE 2—Occupational diseases and transit injuries as a proportion of all occupational injuries, Brazil, 1970–1987.

separate sites for delivering occupational medical services were maintained. In recent years, especially with the new constitution, other functions such as workplace inspection seem to be moving from the Ministry of Labor to the Ministry of Health, although some reversal of this trend occurred in 1990 under the new government. The effects of this change remain to be seen, but if successful, it offers some promise of decreased intersectoral disputes and a more efficient government role in occupational safety and health. □

An Evaluation of the Impact of Maternity Care Coordination on Medicaid Birth Outcomes in North Carolina

Paul A. Buescher, PhD, Marcia S. Roth, MPH, Dennis Williams, BA, and Carolyn M. Goforth, BSN

ABSTRACT

Background. Care coordination is an important component of the enhanced prenatal care services provided under the recent expansions of the Medicaid program. The effect of maternity care coordination services on birth outcomes in North Carolina was assessed by comparing women on Medicaid who did and did not receive these services.

Methods. Health program data files, including Medicaid claims paid for maternity care coordination, were linked to 1988 and 1989 live birth certificates. Simple comparisons of percentages and rates were supplemented by a logistic regression analysis.

Results. Among women on Medicaid who did not receive maternity care coordination services, the low birth weight rate was 21% higher, the very low birth weight rate was 62% higher, and the infant mortality rate was 23% higher than among women on Medicaid who did receive such services. It was estimated that, for each $1.00 spent on maternity care coordination, Medicaid saved $2.02 in medical costs for newborns up to 60 days of age. Among the women who did receive maternity care coordination, those receiving it for 3 or more months had better outcomes than those receiving it for less than 3 months.

Conclusions. These results suggest that maternity care coordination can be effective in reducing low birth weight, infant mortality, and newborn medical care costs among babies born to women in poverty. (*Am J Public Health.* 1991;81:1625–1629)

Introduction

Factors associated with infant mortality and morbidity and with handicapping conditions in infants and young children are numerous and complex. It has been documented repeatedly, however, that the single most important factor contributing to infant death and disability is low birth weight.[1,2] Avoiding unintended and high-risk pregnancies is an important first line of prevention.[3] Experience proves that the incidence of low birth weight can also be reduced through the use of early, continuous, and comprehensive prenatal care.[4]

In October 1987, in response to concerns over North Carolina's high infant mortality rate, the state Medicaid program was expanded to improve access to health care and support services for low-income pregnant women and young children. This expansion, referred to in North Carolina as the Baby Love Program, was developed and implemented by the Division of Maternal and Child Health and the Division of Medical Assistance, in cooperation with the Office of Rural Health and Resource Development. Two key elements of the Baby Love Program were expansion of Medicaid eligibility to 100% of the federal poverty level and reimbursement for maternity care coordination (case management) services for Medicaid-eligible pregnant women.

Maternity care coordination is the cornerstone of the Baby Love Program in that it is aimed directly at eliminating barriers to client use of services. Maternity care coordinators help eligible women receive services that address not only medical but also nutritional, psychosocial, and resource needs. Coordinators also provide pregnant women with social and emotional support, which may lead to stress reduction and the adoption of healthful behaviors during pregnancy. In North Carolina, all pregnant women certified for Medicaid are eligible for maternity care coordination services. This entire population is considered to be at high risk for poor pregnancy outcomes, owing to either medical or psychosocial risk factors, or a combination of the two.

Previous studies have shown that comprehensive prenatal care, which includes various nonmedical support services, improves birth outcomes among women in poverty.[4,5] The purpose of this evaluation is to determine if the receipt of maternity care coordination services by Medicaid-eligible clients improves birth outcomes. Maternity care coordination, which began in late 1987, was introduced as a statewide program. Because the program was not piloted in a limited geographic area of the state, it was important to conduct the evaluation before the statewide system was fully developed to ensure that a comparison group of nonrecipients could be obtained.

The period of evaluation was 1988 and 1989, the first 2 years of program im-

plementation. During this time, more than 15 000 women received maternity care coordination, two thirds of whom were served in 1989. For the 2-year period, the mean month of pregnancy in which maternity care coordination began was 5.6. In 1988, the start-up year, the mean month of service initiation was 6.0; in 1989, this had improved to 5.4.

Methods

North Carolina resident live births to women on Medicaid during calendar years 1988 and 1989 were examined to compare birth outcomes of those women who received maternity care coordination services with the outcomes of those who did not. The birth outcomes compared were low birth weight (less than 2500 g), very low birth weight (less than 1500 g), infant mortality, and newborn medical care costs (which are, to some degree, a surrogate for infant morbidity). The effect of maternity care coordination on prenatal participation in the Special Supplemental Food Program for Women, Infants and Children (WIC) was also examined.

To carry out this evaluation, we linked a number of data files to 1988 and 1989 birth certificate records. Using the baby's name, date of birth, hospital of birth, and other information, we matched birth records to newborn hospital claims paid by Medicaid to identify "Medicaid" births and achieved a matching rate of over 95%. Then, using the baby's Medicaid ID number retained from this step, we extracted all claims paid for any service (inpatient, outpatient, medications, etc.) *beginning* within 60 days of birth and we summarized the costs. If a hospitalization began within 60 days of age but extended beyond that time all costs for the hospitalization were counted. These costs were examined only for services beginning within 60 days of birth because maternity care coordination would be expected to have its major impact on early infant morbidity. Also, the babies of women receiving maternity care coordination are automatically eligible to remain on Medicaid for 60 days after birth; thus, there is no problem of attrition within this group due to discontinued eligibility.

Using the mother's name and date of birth, we matched birth records to claims paid for maternity care coordination to identify births for which the service was received. Total amount paid for care coordination was retained from this step. Then we summarized prenatal visit records from the public health department client information system in North Carolina and, again using mother's name and date of birth, matched them to the birth records to identify those births that received prenatal clinic care in health departments. And we used mother's name and date of birth to match births with WIC records to identify women receiving this nutritional service during the prenatal period. Finally, infant death records were linked to the 1988 and 1989 birth cohorts as part of routine vital records processing, and this allowed us to assess infant mortality rates.

In matching the maternity care coordination, health department, and WIC records to the 1988 and 1989 births, we achieved a matching rate of about 90%. Incomplete matching of the maternity care coordination records has resulted in some maternity care coordination recipients being counted as nonrecipients. To the extent that maternity care coordination does improve birth outcomes, this incomplete matching has caused the findings shown here to understate the true difference between the two groups.

Within the group of Medicaid births identified by a matching Medicaid newborn hospital claim, we compared birth outcomes between women with and without maternity care coordination. Multiple births (twins etc.) and births with no prenatal care, the latter of which would all fall into the not-care-coordinated group and thus bias the results, were excluded from the analysis to increase the validity of the comparisons. Simple comparisons of percentages and rates were supplemented by a logistic regression analysis. This analysis assessed the effect of maternity care coordination on birth outcomes while statistically controlling for differences between the two groups on other measurable risk factors.

We also compared outcomes for women on Medicaid with different lengths of maternity care coordination, as defined by months of participation (less than 3 months vs 3 months or more). Because there could be some bias in the results by length of participation, given that a woman who delivers prematurely will thereby have a shorter period of care coordination participation, we compared low birth weight rates between these groups for full-term births (at least 37 weeks gestation). As another way to control for this gestational age bias, we examined birth outcomes by length of maternity care coordination participation in weeks as a *percent* of length of gestation in weeks (less than 25%, 26 to 50%, and more than 50%).

Previous studies have shown that prenatal care provided in public health clinics is very effective in reducing adverse birth outcomes among women in poverty.[4,5] Therefore, it might be argued that women receiving maternity care coordination would have had better birth outcomes simply because most of them received prenatal care in public health departments, particularly in the first years of the program; whereas many of the women not receiving maternity care coordination received their prenatal care from another provider. To control for this potential source-of-prenatal-care bias, we broke out the basic results of this study separately for public health department patients and for patients of other prenatal care providers. We also used source of prenatal care as a control variable in the logistic regression analysis.

Results

Measures in the top part of Table 1 reveal that, among women on Medicaid not receiving maternity care coordination services, the low birth weight rate was 21% higher, the very low birth weight rate was 62% higher, and the infant mortality rate was 23% higher than among women on Medicaid who did receive such services. Further, the average cost of medical care for the baby in the first 60 days of life was $277 higher for infants of women not receiving maternity care coordination services, while prenatal WIC participation was substantially lower for this group.

The results in Table 1 are also shown separately for women receiving prenatal clinic care in public health departments and for those receiving prenatal care from other providers. These results are similar to those for the total: the women receiving maternity care coordination had consistently better outcomes in both prenatal care groups. Therefore, the better birth outcomes for women receiving maternity care coordination are not just a result of most of them receiving prenatal care in the public health setting.

For the total group of 15 526 women receiving maternity care coordination, Medicaid paid an average of $137 for the care coordination services. Dividing the difference in average newborn costs of $277 by this $137 results in an estimated $2.02 saved by Medicaid in all medical costs for services beginning within 60 days of age for each $1.00 spent on maternity care coordination. An average net savings of $140 ($277−$137) for each of the 15 526 women receiving care coordination trans-

lates into a total estimated savings of $2,174,000 for 1988 to 1989.

Table 2 shows that the women on Medicaid who received maternity care coordination services were at somewhat *higher* risk for several of the maternal characteristics often associated with low birth weight and infant death (characteristics derived from the birth certificates). Therefore, their better birth outcomes shown in Table 1 do not appear to be owing to favorable status on these measured risk factors. This slightly higher demographic risk may be related to the fact that some health departments initially targeted maternity care coordination to teens and other high-risk groups because insufficient resources were available to provide this service to all Medicaid-eligible women. Yet the pregnant women who received maternity care coordination had better birth outcomes despite higher levels of these other risk factors.

Table 3 presents the results of a logistic regression analysis that compared the independent effects of various risk factors on low birth weight and infant mortality. Race, age of mother, and medical risk factors during the pregnancy were the strongest predictors of adverse outcomes. After controlling for all the other risk factors shown in Table 3, including source of prenatal care, women not receiving maternity care coordination services were found to be 1.22 times as likely to have had a birth under 2500 g as women receiving the service, 1.48 times as likely to have had a birth under 1500 g, and 1.20 times as likely to have had an infant death. Both low birth weight odds ratios have 95% confidence intervals with the lower limit above 1.00.

So far in this analysis, maternity care coordination has been treated as present or absent, regardless of the length of care coordination for those receiving the service. In Table 4, the women receiving care coordination are divided into two groups: those beginning care coordination 3 or more months before giving birth and those receiving care coordination for a shorter period of time. For each measure in Table 4, the women who received care coordination longer had better outcomes.

The potential problem of bias due to preterm delivery shortening the length of service participation was addressed in two ways. First, we compared only full-term births. Among full-term births, women with care coordination for 3 or more months had a low birth weight rate of 3.81% compared with a rate of 5.07% for those receiving care coordination for less than 3 months ($P < .001$). Second, we compared birth outcomes by percent of the pregnancy for which maternity care coordination was received. Table 5 shows these results. Women who received maternity care coordination for more than 50% of their pregnancy had substantially lower rates of low birth weight, very low birth weight, and infant mortality. These results are further evidence that maternity care coordination services for pregnant women on Medi-

caid in North Carolina are effective in reducing adverse birth outcomes.

Discussion

These results strongly suggest that maternity care coordination did improve the outcomes of live births to women on Medicaid in 1988 and 1989, the first 2 years of the Baby Love Program in North Carolina. The apparently large impact of maternity care coordination on very low birth weight is especially important. Even modest reductions in this relatively rare event can make prevention programs cost-effective, given the very high rates of morbidity and the use of medical care among these infants.

The results by degree of maternity care coordination (Tables 4 and 5) provide additional evidence that care coordination improved birth outcomes among these women in 1988 and 1989. Longer participation was associated with better birth outcomes, even after controlling for potential gestational age bias.

Women who receive maternity care coordination are encouraged to obtain a variety of services for which they may be eligible, such as Aid to Families with Dependent Children, job training, social work, transportation, food stamps, and housing assistance. Many of these services are not directly reimbursable by Medicaid. The maternity care coordinator acts as an advocate, assisting the pregnant woman in navigating a complex service system with often confusing application procedures so that such services may be obtained. The visit schedule is determined by the client's need and may be much more frequent than the minimum required level of one encounter per month.

One example of the impact of this assistance was prenatal WIC participation. We found that those women on Medicaid with maternity care coordination were significantly more likely to receive this important nutritional service than those without it. In addition, data for 1988 and 1989 from the North Carolina Health Services Information System show that, among public health department patients, women receiving maternity care coordination were more likely to have had a postpartum family planning exam (68% vs 39%) and to have had their newborns receiving well baby care (65% vs 25%) and WIC (77% vs 36%) than women not receiving care coordination.

In a study such as this, in which it was not possible to randomize patients into treatment and control groups, there is always the possibility of selection bias. Women who would have had better birth outcomes anyway may have been drawn for various reasons into the maternity care coordination group. Conversely, women who have experienced previous adverse pregnancy outcomes may have been channeled into care coordination because of their high-risk status. We have done our best to statistically control for *measurable* differences between the Medicaid women who received care coordination and those who did not, although full comparability is never possible. All the women on Medicaid giving birth in 1988 and 1989 had family incomes below 100% of the federal poverty level, so this was a relatively homogeneous

group in economic terms. The issue of provider selection is also salient. The maternity care providers who most actively got their patients into care coordination in the program's first years may have been among those with the strongest prenatal care programs. It is important to note, however, that the providers who implemented the service during 1988 and 1989 represented rural and urban counties and different geographic regions of the state.

The results of this study must be placed in the context of an early evaluation of a statewide system for maternity care coordination services. During 1988 and 1989, only 31% of eligible women on Medicaid received maternity care coordination. In addition, many providers were still in a start-up phase, lacking the full resources needed for the program. A goal of the Baby Love Program is to develop the service capacity necessary for providing care coordination to all eligible women. Therefore, further evaluation of maternity care coordination is needed to validate and extend the results of this study.

Low birth weight and infant mortality are serious problems in North Carolina and the United States and result from a variety of social, economic, and health care factors. Prenatal care is one important means of addressing these problems. However, there is growing evidence that, for women living in poverty, simply financing more prenatal medical visits is not enough.[7] Low-income pregnant women must also be supported in their efforts to meet basic needs such as housing, transportation, food, education, and health care. Maternity care coordination can help them meet these needs by ensuring the receipt of both medical and nonmedical services. This study suggests that maternity care coordination can be very effective in reducing low birth weight, infant mortality, and medical care costs among babies born to women in poverty. □

Call for Nominations: 1992 Healthtrac Prize For Improvement of Health

The Healthtrac Prize is for major achievement in health improvement, unrestricted as to field, with emphasis upon recent contributions to health in the United States, with the general criteria of achievement of the greatest good for the greatest number. It is intended for that individual who has done the most to improve health, as judged by an expert and prestigious Advisory Board.

The Prize could be awarded to a scientist, an educator, a program innovator, an activist, a public figure, a private citizen, or any other person who has made a significant contribution to improvement of the public health.

The Prize is intended to celebrate important work and bring it to public recognition so as to reward the efforts which have improved health, to increase the impact of the work, and to stimulate others to emulate the role models represented by the Prize recipient. Nominations are due April 1, 1992. The award amount is $50 000.

For further information and nomination procedures, write to Dr. James F. Fries, Healthtrac Foundation, 525 Middlefield Road, Suite 250, Menlo Park, CA 94025.

The Importance of Assessing the Fit of Logistic Regression Models: A Case Study

David W. Hosmer, PhD, Scott Taber, MS, and Stanley Lemeshow, PhD

ABSTRACT

Background. The logistic regression model is being used with increasing frequency in all areas of public health research. In the calendar year 1989, over 30% of the articles published in the *American Journal of Public Health* employed some form of logistic regression modeling. In spite of this increase, there has been no commensurate increase in the use of commonly available methods for assessing model adequacy.

Methods. We review the current status of the use of logistic regression modeling in the *American Journal of Public Health*. We present a brief overview of currently available and easily used methods for assessing the adequacy of a fitted logistic regression model.

Results. An example is used to demonstrate the methods as well as a few of the adverse consequences of failing to assess the fit of the model. One important adverse consequence illustrated in the example is the inclusion of variables in the model as a result of the influence of one subject.

Conclusions. Failure to address model adequacy may lead to misleading or incorrect inferences. Recommendations are made for the use of methods for assessing model adequacy and for future editorial policy in regard to the review of articles using logistic regression. (*Am J Public Health.* 1991;81:1630–1635)

Introduction

Modern public health research has become increasingly reliant on sophisticated statistical modeling techniques to assess the effect of new health programs, the impact of risk factors on disease, the effects of health behaviors, and a host of other public health concerns. Many such analyses involve an outcome, or dependent, variable that is dichotomous (present/absent, yes/no, live/die, etc.), and in these studies the logistic regression model has become the statistical model of choice. The reasons for this are the ease of interpretation of the estimated coefficients as "adjusted log odds ratios," the ability to estimate the probability that a particular subject will develop the outcome, and the wide availability of easily used and reliable software to perform the computations. It is now common to find, in an article using logistic regression, a table of estimated coefficients, estimated odds ratios, and associated confidence limits for the odds ratio.

The validity of inferences drawn from modern statistical modeling techniques depends on the assumptions of the statistical model being satisfied. A critical step in assessing the appropriateness of the model is to examine its fit, or how well the model describes the observed data. Very few articles in subject-matter journals make any mention of having carried out this important step in model development. Without such an analysis, the inferences drawn from the model may be misleading or even totally incorrect. Unfortunately, in some instances the results of fitting a logistic regression model have been published when the model contained serious errors that would have been detected had any attempt at goodness of fit (GOF) been performed. The logistic regression model is a powerful statistical tool, but it must be used with caution.

The goal of this paper is to present an overview of a few easily employed methods for assessing the fit of logistic regression models. An example is used to demonstrate the use of the methods and the consequences of failing to assess fit. Much of what will be presented here is described in detail in texts by Hosmer and Lemeshow[1] for logistic regression modeling and others (e.g., Kleinbaum, Kupper, and Muller[2]) for linear regression modeling. The background provided in this paper should be sufficient to allow readers to consult these texts and others for more detail.

Assessments of Goodness of Fit in the American Journal of Public Health

In order to get some idea of the frequency of use of logistic regression and methods for assessment of GOF, we reviewed the contents of the *American Journal of Public Health (AJPH)* for the calendar years 1985 through 1989. The journal's articles and brief reports were considered separately. Each published article or brief report was considered in terms of whether or not logistic regression was used and, if it was used, whether or

The authors are with the School of Public Health of the University of Massachusetts/Amherst.

This paper was submitted to the journal December 28, 1990, and accepted with revisions May 6, 1991.

not any assessment of GOF was performed. The results are presented in Table 1.

Overall, approximately 20% (113) of the 579 articles reviewed used logistic regression. It is interesting to note that almost 40% (45) of the papers using logistic regression appeared in 1989. Only about 5% (6) reported that any assessment of model adequacy had been performed. Logistic regression is less frequently used in brief reports (about 6%), with about the same level of attention to assessing model adequacy (about 4%).

There has been a striking increase in the use of logistic regression, but there has been no increase in the frequency of assessment of the adequacy of the model even though the techniques are now readily available in many software packages. Inferences from analyses where there has been no assessment of GOF should be viewed with some skepticism.

TABLE 1—Use of Logistic Regression (LR) and Goodness of Fit (GOF) Measures in the *American Journal of Public Health*: 1985–1989

	Articles Using LR		LR Articles Using Any Type of GOF		Brief Reports Using LR		LR Brief Reports Using Any Type of GOF	
Year	%	n	%	n	%	n	%	n
1985	16.5	85	14.3	14	2.3	86	0.0	2
1986	12.0	100	8.3	12	5.2	58	0.0	3
1987	16.0	125	0.0	20	5.3	75	0.0	4

1989	31.0	145	2.2	45	10.5	76	0.0	8
Total	19.5	579	5.3	113	6.1	379	4.4	23

What Is Goodness of Fit?

Much of the lack of effort in assessing the fit of any statistical model, and logistic regression in particular, may be traced to a general misunderstanding and confusion by many users of regression methods as to what GOF is and what its role is in the modeling process.

In any statistical analysis where regression methods are employed, the goal is to obtain a mathematical model that describes the relationship between observations of the outcome or dependent variable, to be denoted as y, and a collection of independent variables, to be denoted in aggregate, without reference to their number and measurement scale, as x. A convenient way to conceptualize the model is to think of the value of the dependent variable as being composed of two parts: (1) the systematic component and (2) the error component. The systematic component is the mathematical function of the independent variables that characterizes the "average" value of y among subjects with values of the independent variables (in the model) x. The error component represents how much an individual subject's value of y differs from the "average." (We use "average" in a generic sense because, for some models, such as logistic regression, we model a transformation or function of the mean of y given x.) For example, a linear regression model for systolic blood pressure for adults might contain as independent variables height, weight, gender, and age. This portion of the model provides an estimate of the mean systolic blood pressure as a function of the variables in the model. For example, the model might give a value of 120 mm Hg for a 72-in, 160-lb, male, 40-year-old subject. The error portion for an individual measurement would be the difference between the observed value and the mean value produced by the model. The errors are often called residuals since, for many models, they are computed as the difference between the observed and predicted (systematic component) values of the dependent variable. For example, if the actual systolic blood pressure for our hypothetical subject is 110, then the value of the error would be $110 - 120 = -10$. A general formula incorporating the two components is y = systematic component + error component.

The process of "building" the regression model concentrates on the systematic component. This involves the functional relationship between the "average" of y and the content of x, the actual variables in the model. The selection of variables usually involves both biological and statistical criteria since we may include in a model variables that are of known biological importance regardless of their statistical significance. The rationale is that these variables may be needed to adjust the coefficients of other variables in the model, thereby controlling confounding. The statistical focus of model building is on the magnitude of the "slope" coefficients of the variables. Also of concern is that each variable enter the model in the correct scale. For example we should consider, for continuous independent variables, whether or not we need just x, or x^2, or $\log(x)$, etc., in the model. The result of the systematic component is a function that produces predicted or fitted values of the dependent variable. These will be denoted in general by $\hat{y}$. Attention turns to the error component after completion of the systematic component. We call the process of examining the values of the error component, both individually and collectively, assessing the GOF of the model.

Assessing GOF will usually entail two stages: computing a statistic that provides a summary measure of the errors, and examining the individual values of the errors. The summary statistic may be small yet contain individual error components that are large under the assumption of a good-fitting model.

A class of statistics called "regression diagnostics" has been proposed to examine the role of individual subjects in the model. The purpose of regression diagnostics is to aid in identifying subjects who are problematic under the current model. In this paper we consider three types of diagnostic statistics: measures of residual, leverage, and influence. A particular subject may be called to our attention because the model-based prediction of its outcome is not very close to that observed, or if it has an exceptionally large error, or "residual." Methods based on measures of residual will help identify these subjects. A subject may have a configuration of independent variables that is most unusual relative to the rest of the subjects. A measure that is used to identify these subjects is, for a variety of technical reasons, called "leverage." We are also interested in identifying those subjects who have a large effect on the systematic component as expressed by the magnitude of any of the estimated coefficients in the model. The contribution of an individual observation to the magnitude of a coefficient depends on both its residual and its leverage. These are called "influence" measures, and one form of them will be presented later.

Regardless of which diagnostic statistic is used, we must be able to ascertain which values are large. In general, histo-

grams and scatterplots are the most effective ways to view the distributions of these statistics, since what is of importance is their relative magnitude. For some types of models, such as linear regression, there are fixed cutpoints that may be used to identify an exceptionally large value for a diagnostic statistic. For other models, such as logistic regression, there are no such cutpoints, so graphical methods take on added importance. Unless a study is small, a listwise printout of the diagnostics will be too long and will not adequately present relative size.

After considering summary measures and regression diagnostics, we will have specific evidence about the fit of the proposed model. We will have an indication of how well it fits overall and how sensitive it is to individual subjects. The issues faced in dealing with problematic subjects identified using regression diagnostics will differ from study to study. Whatever approach is taken, it is important that subjects never be deleted solely on the basis of statistical criteria. In all cases, the methods used for identification and criteria for exclusion should be made clear and all subjects deleted specifically noted.

Assessing the Fit of a Logistic Regression Model

In this section we present a brief review of several basic methods for assessing the fit of a logistic regression model. For greater detail, the reader is referred to Hosmer and Lemeshow.[1] Before beginning, we need some notation to indicate the data and the fitted model.

Assume that we have n independent observations denoted by $(y_i, \boldsymbol{x}_i)$, $i = 1, \ldots, n$ where i indicates the specific subject (observation), y_i is equal to zero when the outcome is absent and is equal to one when it is present, and $\boldsymbol{x}_i = (x_{i1}, x_{i2}, \ldots, x_{ip})$ contains the values of the independent variables in the model. The fitted value from the logistic regression model will be indicated by $\hat{y}_i = \hat{\pi}_i$ ($\hat{\pi}_i$ is the estimated probability that $y_i = 1$ for subject i) and is defined by the equation

$$\hat{\pi}_i = \frac{e^{\hat{g}_i}}{1 + e^{\hat{g}_i}},$$

where $\hat{g}_i = \hat{\beta}_0 + \hat{\beta}_1 x_{i1} + \hat{\beta}_2 x_{i2} + \ldots + \hat{\beta}_k x_{ik}$ is the sum of the estimated coefficients multiplied by the values of the independent variables for the ith subject.

We begin our discussion of assessing GOF by considering two forms of the error component for a fitted logistic regression model and their aggregate statistics. One statistic is the deviance, D, also used in model building. The deviance is given by the equation

$$D = \sum_{i=1}^{n} d_i^2,$$

where the individual components, d_i, are called the "deviance residuals." Under the assumptions in this paper, if $y_i = 1$, then

$$d_i = \sqrt{2|\ln(\hat{\pi}_i)|},$$

and if $y_i = 0$, then

$$d_i = \sqrt{2|\ln(1 - \hat{\pi}_i)|}.$$

Another summary statistic, similar to the deviance, is the Pearson chi-square statistic, which is defined as

$$\chi^2 = \sum_{i=1}^{n} r_i^2,$$

where

$$r_i = \frac{(y_i - \hat{\pi}_i)}{\sqrt{\hat{\pi}_i(1 - \hat{\pi}_i)}}$$

and the individual components, r_i, are called the "Pearson residuals." The Pearson residuals form the basis of many of the logistic regression diagnostic statistics.

The summary statistics D and χ^2 each have degrees of freedom approximately equal to $n - (p + 1)$, but unfortunately do not have an easily interpreted distribution under the assumptions of this paper, which are typical of most practical applications of logistic regression. The fact that these statistics do not follow a chi-square distribution under the hypothesis that the fitted model is, in fact, a correct model may be motivated by thinking of them as being the likelihood ratio chi-square or Pearson chi-square statistic computed from a contingency table with two rows ($y = 1$ or 0) and n columns (subjects) where the column totals are each equal to 1. The estimated expected values for the $y = 1$ row are $\hat{\pi}_i$ and, in the $y = 0$ row, $1 - \hat{\pi}_i$. Thus, any reasonable rule for large expected values would not hold and, under the assumptions of this paper, any P values that a computer program may print for these statistics should not be used. About all we can do in the way of assessing fit is to compare their values with the degrees of freedom.

One strategy that is often employed in dealing with a contingency table with small expected values is to pool biologically similar groups until the resulting categories have large enough expected values. This idea of pooling is the basis of a GOF statistic (see Hosmer and Lemeshow,[3] Lemeshow and Hosmer,[4] and Hosmer, Lemeshow, and Klar[5] for more details). This statistic is obtained by forming 10 groups of equal size containing the deciles of the fitted values. Observed and expected values are calculated by summing the estimated logistic probabilities and observed values of the outcome variable in the usual fashion. This statistic has been shown (see Hosmer and Lemeshow[3]) to follow a chi-square distribution with eight degrees of freedom when the fitted model is the correct model. This statistic is computed by a few computer software packages. The reader is referred to Hosmer and Lemeshow[1] for details on the computation of this statistic.

Any assessment of GOF should begin with the evaluation of the deviance, Pearson chi-square statistic, and, if possible, a decile-based GOF statistic. This should be followed by a careful inspection of the individual regression diagnostics to be described.

Pregibon[6] extended linear regression diagnostics to logistic regression. We present three of these diagnostics that we have found to be adequate for most studies and that may be easily computed when not provided by the computer program. As noted earlier, diagnostic statistics are of three types—leverage, residual, and influence.

The leverage of an observation was originally formulated in linear regression to measure how extreme a subject's values of the independent variables were, relative to the rest of the subjects in the study. It turned out to be a rather natural measure of the distance between an individual's values of $\boldsymbol{x}$ and the mean, $\bar{\boldsymbol{x}}$. Thus, in linear regression, the further $\boldsymbol{x}$ is from $\bar{\boldsymbol{x}}$, the greater the leverage. Leverage in logistic regression depends on weights based on the estimated logistic probability and on the distance of an observation from the mean. Define the leverage for the ith subject as $h_i = v_i l_i$, where $v_i = \hat{\pi}_i(1 - \hat{\pi}_i)$ and l_i is proportional to the distance of $\boldsymbol{x}_i$

to $\bar{x}$. The term l_i increases the further x is from $\bar{x}$. Interpretation of v_i requires some generalization for fitted logistic models. In practice, the estimated logistic probabilities, $\hat{\pi}$, either increase or decrease as a function of the independent variables. Thus, the further x is from $\bar{x}$, the larger or smaller is the estimated probability. Hence, while l_i is increasing, v_i is decreasing and approaches zero as $\hat{\pi}_i$ goes to either zero or one. The net effect is that the leverage, considered as a function of $\hat{\pi}_i$, appears quadratic in the approximate range of 0.15 to 0.85 but decreases to zero rapidly in the range of $\hat{\pi}_i < 0.15$ and $\hat{\pi}_i > 0.85$. Hence, those observations that are furthest in distance from $\hat{\pi}_i$ may have the lowest leverage. This is in direct contrast to the situation in linear regression. Maximum leverage in logistic regression tends to occur when $\hat{\pi}$ is around 0.2 or 0.8. This point will be demonstrated in the example in the next section.

Because the behavior of the leverage is closely tied to the magnitude of the estimated logistic probability, we argue that we may use the value of $\hat{\pi}$ as an indirect measure of its value in the sense that by knowing the value of $\hat{\pi}$ we know whether the leverage is expected to be either large or small. Hence, a plot of the value of leverage vs $\hat{\pi}$ assists in determining the regions where the leverage is largest.

The Pearson residuals are somewhat easier to visualize and compute than the deviance residuals, and their respective behavior is quite similar. In linear regression, we may be interested in the sign of the residual as well as its magnitude. However, in logistic regression the sign of the residual is determined by the value of y_i, as it is positive for those $y_i = 1$ and negative for those $y_i = 0$. A measure that allows us to easily determine the sign of the residual and also to more clearly see its magnitude is the amount by which χ^2 would change if the ith subject had been deleted from the model. We label this quantity Δx^2 and define it as

$$\Delta x_i^2 = rs_i^2,$$

where rs_i is the standardized Pearson residual defined by the equation

$$rs_i = \frac{(y_i - \hat{\pi}_i)}{\sqrt{\hat{\pi}_i(1 - \hat{\pi}_i)(1 - h_i)}}.$$

We can see that Δx^2 will be large when the model does not "fit" (i.e., when $y_i = 1$ and $\hat{\pi}_i$ is small, or when $y_i = 0$ and $\hat{\pi}_i$ is large). As is shown in the next section, a plot of Δx^2 vs $\hat{\pi}$ demonstrates this behavior quite clearly.

TABLE 2—Estimated Coefficients, Estimated Standard Errors, and *P* Values for the Fitted Logistic Regression Model

Variable	Estimated Coefficient	Estimated Standard Error	*P* Value
CHEM	0.526	0.249	.035
AGE	1.397	0.447	.002
SMOKE	−0.907	0.327	.006
TYPE	−1.095	0.410	.008
CHEM × TYPE	2.861	1.128	.011
Constant	−1.704	0.468	<.001

$D = 293.1$
$\chi^2 = 283.7$
$df = 279$
$\hat{C} = 22.1$, $df = 8$, $P = .005$

The effects of leverage and residual are combined to yield a diagnostic that expresses the effect of each subject on the estimated coefficients in the model. This measure was originally formulated by Cook[7] for use in linear regression and is often called "Cook distance" in regression applications. It approximates the change in the coefficient estimates due to the exclusion of the ith subject. Some programs provide this measure for each coefficient in the model, but we have found this to be unnecessarily detailed and use an overall measure to identify influential subjects. The exception is the case where there is a single coefficient in the model that is of primary importance, such as an epidemiologic study of a single risk factor. The effect on the individual coefficients may be determined by fitting a model excluding suspected influential subjects. The form of Cook distance that we prefer is given by the equation

$$\Delta\hat{\beta}_i = \Delta x_i^2 \times \frac{h_i}{(1 - h_i)}.$$

We recommend that Cook distance also be plotted vs the estimated logistic probability, as this allows one to determine the contribution of both residual and leverage to the value.

In the next section we illustrate the use of the methods for assessing the fit of a model.

A Case Study

In order to provide a realistic example, we analyze some of the data being used by a study conducted in the School of Public Health at the University of Massachusetts (X Hu, personal communication, 1989). The results of this study have not been published, so we refer to the principal variables in a generic sense. This study assessed the association between exposure to a chemical (CHEM) and the occurrence of certain symptoms (SYMP = 0 [no] or 1 [yes]) in an industrial cohort. Other important variables were determined to be whether or not the subject was a current smoker (SMOKE = 0 [no] or 1 [yes]), whether or not the subject was 40 years or older (AGE = 0 [< 40] or 1 [≥ 40]), and which of two forms of the chemical the subject was exposed to (TYPE = 0 or 1). This particular phase of the study involved 285 males, of which 93 had symptoms and 192 did not. Considerable effort went into model development to identify these as the key variables. Issues surrounding variable selection and model development have been discussed in Hosmer and Lemeshow[1] as well as in a review paper by Greenland.[8] The first model contained the main effects for each variable as well as the interaction between the chemical and its type. The results are provided in Table 2.

We can see that while D and x^2 suggest that the model might be appropriate (i.e., they are not too much larger than their degrees of freedom), the GOF statistic, $\hat{C}$, provides evidence for some lack of fit. The diagnostic plots discussed above will identify those subjects who are poorly fit and/or influential. The plots for the model in Table 2 are shown in Figures 1 through 3.

In Figure 1 we see that the points with the highest leverage values have moderate estimated logistic probabilities. As expected, the subject with the largest leverage has an estimated probability in

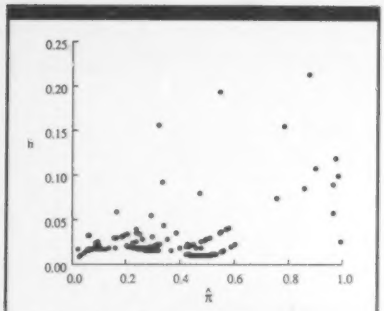

FIGURE 1—Plot of leverage vs the estimated logistic probabilities for the fitted model in Table 3.

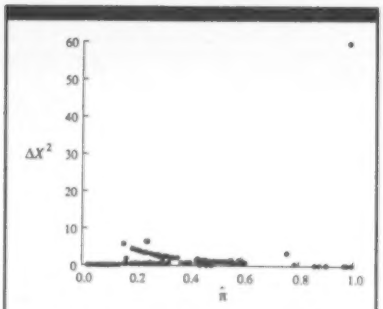

FIGURE 2—Plot of ΔX^2 vs the estimated logistic probabilities for the fitted model in Table 3.

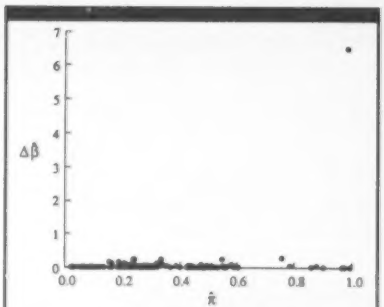

FIGURE 3—Plot of $\Delta\hat{\beta}$ vs the estimated logistic probabilities for the fitted model in Table 3.

the region around 0.8. The leverage decreases to zero as $\hat{\pi}$ approaches zero and one.

In Figure 2 the plot of the change in Pearson chi-square, Δx^2, vs $\hat{\pi}$ shows one subject who is extremely poorly fit with a value of around 60.

In Figure 3 the plot of the influence diagnostic, $\Delta\hat{\beta}$, calls our attention to this same subject. We note that this subject was not one with high leverage, indicating that the influence is primarily due to lack of fit.

At this point we examine the particular subject and see whether we can determine why he was so poorly fit. This particular individual was over 40, smoked, and had the highest level of exposure to the chemical but displayed no symptoms (i.e., $y = 0$ but $\hat{\pi}$ was quite large). If the actual data were available to us, we would probably go back to verify the exposure. In all instances, biological plausibility is an issue. Whether or not we ultimately exclude the suspected subject, it is a good idea to fit the model without the subject. The results of this fit yield a model where the estimated coefficients for the type of chemical and the type by chemical interaction are no longer significant. This suggests that a much simpler model containing only AGE, CHEM, and SMOKE could be sufficient. The results are given in Table 3.

The summary statistics indicate that the simpler model fits the data quite well when the suspected subject is deleted from the data. Plots of the diagnostic statistics support this observation. At this point, the decision as to what to do about this subject involves biological criteria that we are unable to address.

TABLE 3—Estimated Coefficients, Estimated Standard Errors, and *P* Values for the Fitted Logistic Regression Model Obtained When the Suspect Case Is Excluded

Variable	Estimated Coefficient	Estimated Standard Error	*P* Value
CHEM	2.712	0.520	<.001
AGE	1.645	0.499	.001
SMOKE	−0.914	0.344	.008
Constant	−2.808	0.524	<.001

$D = 272.6$
$x^2 = 248.2$
$df = 280$
$\hat{C} = 7.10$, $df = 8$, $P = .53$

Summary

Modern computer technology has put powerful statistical tools at the disposal of many researchers. Logistic regression is one such technique that can yield elegant results with a biologically relevant interpretation. However, the simple act of running a logistic regression package in no way guarantees that (1) the logistic model was the appropriate model to use and/or (2) the model accurately reflects the experience in the data.

Put in another context, in simple linear regression only the most naive investigator would fit a straight line to data without examining a scatterplot to determine whether a line was a reasonable model. Increasingly, researchers are using regression diagnostics to check the assumptions and assess the effect of individual cases on a multiple linear regression. There has been a growing appreciation of the fact that even one or two unusual data points can markedly affect the associations and relationships demonstrated by the vast majority of the subjects in a database. Regression texts note this point and urge that diagnostics be employed as part of any regression analysis.

While the popularity of logistic regression analysis has grown dramatically in the last decade, our review of articles published in the *AJPH* has clearly indicated that researchers may be using the fitted model without checking for its appropriateness or adequacy of fit. In 1989, 31% of the articles published in the *AJPH* used logistic regression methods, but only 2% of those used some form of GOF.

Logistic regression diagnostics provide powerful tools in the search for an accurate and useful model. Computer software packages are making these diagnostic statistics more readily available, and researchers will find that making an effort to employ them will greatly enhance their understanding of their data and enable them to build more accurate and useful statistical models.

We have shown in this paper that there are a few easily employed methods that will detect serious inadequacies in a fitted logistic regression model. The clear implication is that if a logistic model does not fit, then it does not reflect the data and thus should not be published. The editors of *AJPH* should require that authors provide some assurance that all logistic regression models have been checked for fit

and adequacy before accepting inferences based on these models. □

Call for Abstracts

A conference entitled the "International Child Day Care Health: Science, Prevention, and Practice," will be held at the Hotel NIKKO Atlanta, Atlanta, Georgia on June 15–17, 1992. The objective of this conference is to provide structured and informal opportunities to exchange information, skills, knowledge, and experiences related to child day care health. Presentations and discussion will focus on three major themes: (1) Child Day Care Health; (2) Meeting the Needs of Children and Care Givers; and (3) Translating Science into Practice. Submissions are encouraged for concurrent scientific sessions on infectious diseases; injuries and hazards; health promotion; children with special needs and disabilities; environmental health; developmental and psychological aspects; occupational health; impact of regulations, standards, accreditation, and training; and economics. The abstract deadline is January 15, 1992. For more information contact Lillian Glickman at Pace Enterprises, Inc. at (404) 633-8610 or FAX (404) 633-8745.

Overcoming Denial and Increasing the Intention to Use Condoms through the Induction of Hypocrisy

Elliot Aronson, Carrie Fried, and Jeff Stone

ABSTRACT

Feelings of hypocrisy were induced in college students to increase condom use. Hypocrisy was created by making subjects mindful of their past failure to use condoms and then having them persuade others about the importance of condoms for AIDS prevention. The induction of hypocrisy decreased denial and led to greater intent to improve condom use relative to the control conditions. The implications of these findings for AIDS prevention are discussed. (*Am J Public Health.* 1991;81:1636–1638)

Introduction

Now that the acquired immunodeficiency syndrome (AIDS) epidemic is making significant inroads into the heterosexual, nonintravenous drug–using, young adult population,[1] it is vital that we convince this group to practice safer sex. The intervention of choice, thus far, has primarily been information campaigns that rely heavily on fear. Unfortunately, social psychological research has shown that fear does not always lead people toward rational behavior; it may instead trigger denial. Indeed, recent surveys have shown that, although most young adults believe that AIDS is a serious problem, they have trouble believing it is *their* problem. We have found that denial is caused by fear of AIDS coupled with a prejudice against using condoms; young people believe condoms are a nuisance that diminishes the romance and spontaneity of sexual encounters. Unless this denial can be overcome, it seems doubtful that we can convince this population to practice safer sex. If they have convinced themselves that they are not at risk, why should they change their behavior?

What kind of intervention might obviate this denial and induce young adults to realize their vulnerability and increase their resolution to practice safer sex? Imagine you are a college student and your younger brother, who is in high school, confides to you that he has become sexually active. How might you respond? You would probably urge him to use condoms. But suppose further that you were then reminded that you, yourself, do not always use condoms. How might this affect you? Recent theorizing[2] suggests that being confronted with the fact that you are not practicing what you preach induces feelings of hypocrisy, which is a form of cognitive dissonance.[3] Cognitive dissonance has been shown to produce "self persuasion," a powerful and relatively permanent form of persuasion.[4] We propose that inducing people to realize they are not practicing what they are preaching cuts off the easy route of denial and forces them to make a more realistic assessment of the risk of AIDS and, ultimately, to take adequate precautions.

Method

To test this hypothesis, it was necessary to manipulate the degree to which subjects were made aware of their own insufficient condom use and the degree to which they took an active role in preaching to others. In a two-by-two laboratory experiment, 40 female and 40 male sexually active young adults were randomly assigned to condition, counterbalanced by gender.

Upon entering the lab, all subjects were told they would be helping to develop an AIDS prevention program. Half the subjects (*high mindful*) were asked to describe fully the situations in their recent past when they failed to use condoms; half of this subgroup then went on to the preach condition. The other half of the subjects (*low mindful*) simply went directly to the preach condition without any reference to their own sexual behavior.

The authors are all with the University of California at Santa Cruz.

Requests for reprints should be sent to Elliot Aronson, Kerr Hall, University of California at Santa Cruz, Santa Cruz, CA 95064.

This paper was submitted to the journal August 30, 1990, and accepted with revisions June 24, 1991.

In the preach condition, half the high mindful and half the low mindful subjects were induced to compose a short speech (from a menu of facts) advocating condom use and to deliver it in front of a television camera. They were told this tape would be shown to high school students as part of an AIDS prevention program. The other half of the subjects (no preach) used the same menu of facts to compose a speech; these subjects rehearsed their speeches silently and were not videotaped. Thus, all subjects were exposed to the same information, but only those in the preach condition believed they were actively persuading others.

All subjects then answered questions about the frequency of their condom use in the past, as well as about their intentions to use condoms in the future. The difference between the two questions can be seen as a measure of how much an individual intends to improve his or her condom use in relation to past behaviors.

Results

The results showed support for the effectiveness of hypocrisy and are summarized in Figure 1. On the first measure, subjects in the hypocrisy condition were more likely to admit to their failure to use condoms enough in the past. This indicates that our procedure enabled subjects to overcome denial. Although a ceiling effect prevented us from documenting any possible differences on the future intentions measure, the difference between responses on the two questions indicates that the hypocrisy condition yielded a better index of improvement than any of the other conditions.

In addition to the immediate measures, we contacted subjects after 3 months and asked them about their recent condom use (Table 1). Because a sizable proportion of the subjects could not be located, statistical testing was inappropriate. Nevertheless, the obvious difference in the size of the means suggests that hypocrisy might be the most effective route to long-term behavior change.

These findings may have important implications for AIDS interventions that rely on the passive reception of communication. Specifically, when it comes to acknowledging personal risk of human immunodeficiency virus infection, simply learning about AIDS does not appear to motivate people to overcome denial and examine their risk objectively. Our information-only condition, which most closely resembles passive information, was the least effective intervention. The people within this category remained in a state of denial and were unwilling or unable to admit that AIDS was a serious threat to them personally. Additionally, learning about AIDS even when the information is directly linked to personal behavior does not appear to motivate people to examine their risk objectively, nor does simply advocating safe sex. Our data suggest that making people aware of their past high-risk behaviors must be accompanied by an engaging activity such as a public advocacy if we want them to overcome denial and adopt safer sexual behavior.

The hypocrisy technique can easily be applied to most secondary school classes on sex education or AIDS prevention. Based on our results, we suggest that lectures be supplemented by small group discussions in which each student is induced to make a public attempt to persuade others about the importance of safe sex and, subsequently, to acknowledge his or her past laxity. □

Knowledge about HIV and Behavioral Risks of Foreign-Born Boston Public School Students

Ralph W. Hingson, ScD, Lee Strunin, PhD, Michael Grady, MD, Nancy Strunk, RN, MS, Robert Carr, MS, Beth Berlin, MS, and Donald E. Craven, MD

ABSTRACT

In 1990, 3049 Boston public middle and high school students were surveyed anonymously in English, Spanish, Vietnamese, Chinese, French, or Haitian Creole. Significantly fewer immigrant students, 35% of those surveyed, knew the principal modes of human immunodeficiency virus transmission. Fewer immigrants reported having sexual intercourse (31% vs 53% of nonimmigrants), but among the sexually active only 38% always used condoms, and more immigrants reported intercourse with intravenous drug users (4% vs 1% of non-immigrants). AIDS education should be taught to immigrant students in their native languages. (*Am J Public Health.* 1991; 81:1638–1641)

Introduction

Sixteen million mainland US residents age 18 and older were born elsewhere.[1] Many are Blacks or Hispanics who moved to urban areas where the incidence of AIDS has been particularly high, e.g., New York City, Miami, and Los Angeles. Little is known about their knowledge of human immunodeficiency virus-1 (HIV-1), drug use, and sexual behaviors.

Studies of adolescents particularly are needed. One fifth of the 186 895 AIDS cases nationally as of September 1991 have been in the 16 to 29-year-old age group.[2] Given the long incubation period of HIV-1, many persons in this age group probably became infected as teenagers.

This study compares middle and high school students in the Boston public schools who were born outside the US mainland with students born in the US concerning knowledge about HIV-1 transmission; beliefs about the number of adolescents who engage in risky sexual practices and drug use; and intravenous (IV) drug use, sexual intercourse, and condom use.

Methods

In May 1990, 3049 students from a random sample of Boston public schools (13/19 middle schools and 9/15 high schools) completed a self-administered questionnaire about these topics in English (n = 2704), Spanish (n = 158), Chinese (n = 45), Vietnamese (n = 50), or French or Haitian Creole (n = 92). Translation and independent back translation ensured accuracy of questionnaire wording.

We attempted to survey all 8th and 10th grade students in selected schools. In response to an informational letter about the survey sent to parents of eligible students, 75 parents (1.5%) requested that their children not participate. On the day of the survey 11% of middle school students and 23% of high school students were absent. Among students in attendance, 81% (n = 1382) in middle schools and 73% (n = 1667) in high schools completed the questionnaires, (overall response rate = 77%). Most nonresponse resulted from teachers not scheduling time to administer the survey. The gender, racial, and ethnic distributions of surveyed students closely matched those enrolled in the 8th and 10th grades in the targeted schools and in the Boston school system (Table 1). The questionnaires were anonymous and were placed by students in

Editor's Note. See related Editorial by Hinman on page 1557.

blank manila envelopes. The response category, "prefer not to answer," was available for sexual and drug questions so students could not interpret the behaviors of fellow students by watching whether students answered each question. Teachers clarified student questions about the survey. Students were provided with an AIDS hotline number and instruction about AIDS was subsequently offered to all students.

Results

Students were asked to specify where they were born and how long they had lived in the United States. Thirty-five percent (n = 1057) of the students surveyed were born outside the US mainland. Half had lived in the United States less than 5 years and 21% for 1 year or less; 330 (11%) were Blacks, 309 (10%) were Hispanics, 252 (9%) were born in Asian countries, 34 (1%) were White, and the balance did not specify either their nationality or race. Twenty-one percent were born in the Caribbean or Cape Verde, 5% in Central or South America, and 8% in Asia.

The immigrant students were older ($P < .0001$): 13% compared to 5% of those born in the United States were 18 years or older. Neither the proportions in middle school or high school nor the gender distribution differed appreciably between those born in the US mainland and elsewhere.

Immigrant students were more likely to worry about getting AIDS, but less likely than US-born students to have talked to parents about AIDS and to know ways to avoid getting AIDS, where to obtain information, or where they could be tested for HIV-1 (Table 2).

Immigrant students were more likely to hold a variety of misconceptions about HIV-1 transmission. They were less likely to know that it can be transmitted by sharing needles, heterosexual intercourse, sex between two men, and sex with someone who looks healthy. They were also less likely to know ways to avoid HIV-1 transmission (Table 3). Further, they were more likely to believe that no one their age who has sexual intercourse uses condoms and that most or all people their age are injecting drugs (Table 4).

Immigrant students were less likely to report ever having had sexual intercourse. However, among those immigrants who were sexually active, a higher percentage reported having had sex with an IV drug user. Regardless of whether they were born in the United States or not, 62% of sexually active adolescents did not consistently use condoms and 2% injected illegal drugs (Table 4).

Hispanics, Blacks, Asians, and Whites born outside the United States were less knowledgeable about HIV transmission than students in these

Use IV drugs past month	2	2	0.96 (0.54–1.71)
Ever shared needles	1	1	0.85 (0.36–2.01)

Note. Place of birth unspecified, n = 29; CI = confidence interval.
[a]Percentage of subsample responding "yes," except as noted.
[b]Percent responding "almost all or most."
[c]Percent responding "none."
[d]Percent responding "all the time."

groups born in the United States (Table 5). Students who had immigrated to the US mainland in the previous year were less knowledgeable about AIDS and more likely to believe that their peers inject drugs and do not use condoms than those who had lived here 5 or more years. These newer immigrants were also more likely to have had sex with an IV drug user and to engage in sexual intercourse without using condoms (Table 6).

Conclusion

While most adolescents nationally[3] and in Massachusetts[4,5] know the principal modes of HIV transmission, those in racial and ethnic minorities are less knowledgeable,[6–9] particularly students from other countries and Puerto Rico now residing in the United States. It should be noted that our study reflects the perceptions and practices of immigrant students in the Boston public schools. Knowledge and behaviors may differ in other cities. The use of self-administered surveys often yields lower response rates and more missing data than in-person interviews. Also, absent students may have been less knowledgeable and more likely to engage in risky behaviors.

Despite these limitations, our findings underscore the importance of offering AIDS education in multiple languages in school systems that serve large immigrant populations. Students born outside the United States may bring varying notions about disease causation, prevention, and treatment, and educators should explore those beliefs in a nonthreatening fashion.[10]

Immigrant students may walk a tightrope between acculturation pressures to assume behaviors they perceive as commonplace among peers born in the United States and parental pressure to retain their cultural values and traditions. Students who immigrated to the United States in the previous year were more likely than those living here longer to believe their peers engage in unprotected sex and use IV drugs. Recent immigrants who want to "fit in" with perceived US social norms may be particularly vulnerable to pressure from other teens or adults to engage in unprotected sex or to use illicit drugs.

These students should be helped to understand that unprotected sex and illicit drug use are not as common as they may suspect. Peer-led instruction from students from their own countries who have lived in the United States for several years might be especially helpful, as would training in skills to resist peer pressure.

TABLE 5—Knowledge about HIV-1 Transmission among Boston Public School Students According to Race and Nation of Birth

	Black		Hispanic		Asian		White		Other	
Question	US (n = 974)	I (n = 330)	US (n = 272)	I (n = 309)	US (n = 52)	I (n = 252)	US (n = 568)	I (n = 34)	US (n = 67)	I (n = 113)
Know										
Ways to prevent getting AIDS	92	78	89	84	92	49	94	77	96	66
Where to get information about AIDS	76	57	68	61	67	30	65	44	80	47
Can get AIDS from										
Sex between men and women	93	87	95	85	96	79	96	84	97	90
Sex between two men	82	82	79	80	82	69	90	88	88	65
Sex with someone who appears healthy	54	46	48	44	73	39	71	50	73	39
Sharing needles	96	85	97	91	100	83	96	85	97	87
Toilet Seats	5	11	7	14	6	13	6	15	2	18
Being in the same room with a person who has AIDS	1	8	2	6	0	15	1	6	0	14

Note. US = survey students born in the mainland United States; I = immigrant students; numbers are percentages of totals answering "yes."

The need for such education is magnified by findings that, like US-born students, most sexually active immigrant students do not use condoms and, although this sexually active group is small in absolute numbers, a higher proportion reported having had sex with an IV drug user compared with US-born students. □

HIV Infection and Risk Behaviors among Intravenous Drug Users in Low Seroprevalence Areas in the Midwest

Harvey A. Siegal, PhD, Robert G. Carlson, PhD, Russel Falck, BS, Ling Li, MBA, Mary Ann Forney, PhD, Richard C. Rapp, MSW, Kathy Baumgartner, MS, William Myers, MS, and Morton Nelson, MD, MPH

ABSTRACT

We studied behavioral factors that place intravenous drug users at risk for the acquisition and transmission of the human immunodeficiency virus (HIV) in a sample of 855 individuals not in drug treatment, living in central and southwestern Ohio. The HIV seropositivity rate for the sample was 1.5%. Three factors were significantly related to HIV infection: homeless shelter residence (odds ratio [OR] = 7.7, 95% confidence interval (CI) = 3.0–20.0), travel to northeastern HIV hyperendemic areas (OR = 5.2, 95% CI = 1.8–15.4), and recent male homosexual or bisexual behavior (OR = 11.2, 95% CI = 2.9–43.9). (*Am J Public Health.* 1991;81:1642–1644)

Introduction

Intravenous drug users (IVDUs) are at high risk for contracting the human immunodeficiency virus (HIV).[1] In the United States, epidemiologic studies have focused primarily on assessing the risk behaviors of IVDUs in high (>15%) HIV seroprevalence areas. Risk factors associated significantly with high HIV seropositivity include the following: minority status, male homosexual or bisexual behavior, a history of sexually transmitted diseases (STDs), frequency of injection, cocaine injection, drug use in shooting galleries, and sharing of drug injection equipment.[2–5] While studies of IVDUs in low seroprevalence areas have identified similar risk behaviors, these have generally not been associated significantly with positive serostatus.[6–9]

This paper first describes the prevalence of HIV risk behaviors reported by 855 active IVDUs in a low seroprevalence area of the Midwest. It then examines the relationships among sociodemographic variables, residence and mobility patterns, drug-use patterns, sexual behaviors, and HIV infection.

Methods

From March 1989 to July 1990, 855 IVDUs were recruited from the streets in the metropolitan areas of Columbus and Dayton, Ohio, by indigenous outreach workers. To be eligible for the study, subjects had to have injected some drug at least once in the previous 6 months, be at least 18 years of age, and not have been in drug treatment in the 30 days prior to data collection.

Data were collected using the AIDS Initial Assessment Instrument (AIA), developed by the National Institute on Drug Abuse for its AIDS outreach and prevention projects. All 855 IVDUs voluntarily agreed to have a sample of their blood screened for HIV antibodies. Serum samples were initially screened using the Abbott enzyme-linked immunosorbent assay. Confirmation tests consisted of Western blotting and were considered positive when antibodies to two of three bands were detected: gp 160/120, gp41, p24.

Based on the results of descriptive statistics, Mantel-Haenszel odds ratios (OR) with 95% confidence intervals (CI) were calculated to compare seropositive and seronegative IVDUs on selected variables. Chi-square tests corrected for continuity were employed to assess significant associations.

Results

Males constituted 75% of the sample. Seventy-eight percent of the sample were Black, 21% were White, and 1% belonged to other racial groups. The median age was 36.

Drug and Needle Use Behaviors

Striking in this sample are the high rates of cocaine use: 79% had injected cocaine in the previous 6 months while 68% reported smoking crack cocaine occasionally, weekly, or daily. Sixty-one percent had injected heroin, and 43% had injected heroin mixed with cocaine (speedball).

About half (49%) reported sharing needles or syringes within the last 6 months. Only 31% reported injecting drugs in a shooting gallery, and almost one quarter (23%) of the IVDUs claimed that they always used a new needle and syringe.

The research for this paper was conducted at Wright State University, School of Medicine, Substance Abuse Intervention Program, Dayton, Ohio; Columbus Health Department, Columbus, Ohio; and Montgomery County Combined Health District, Dayton, Ohio.

[a]Chi-square test corrected for continuity.
[b]For this study northeastern HIV epicenters include New York, NY, Newark, NJ, and Jersey City, NJ.
[c]The AIDS Initial Assessment instrument is designed to assess risk behaviors in the 6 months preceding the interview. If a respondent reports no sexual activity, there is no mechanism to determine sexual orientation. Of the 10 seropositive males, sexual orientation is known for 7 participants: 5 report heterosexual behavior and 2 report homosexual behavior. Given these small numbers, results must be interpreted cautiously.

Sexual Practices

The majority of IVDUs (93%) reported having sexual relations within the previous 6 months; 58% indicated having multiple partners. Almost 40% of the IVDUs reported a history of at least one STD. Of all those IVDUs sexually active in the previous 6 months, 96% reported sexual behaviors that we categorized as heterosexual, 2% as bisexual male (3% female), and 2% as homosexual male (4% female).

HIV Seropositivity and Risk Behavior

The seropositivity rate for the total sample was low—1.5% (13 of 855 subjects). A greater percentage of seropositive subjects injected drugs on a daily basis compared to seronegative participants (54% vs 34%, respectively), reported a higher daily cocaine injection rate (38% vs 17%), and were more likely to live in a homeless shelter (46% vs 10%), to travel to HIV epicenters (31% vs 11%), to have multiple sex partners (78% vs 57%), to have a history of STDs (62% vs 39%), to have ever shared needles or syringes (69% vs 48%), and to use new needles less frequently (7% vs 24%).

Three variables were associated significantly ($P < .05$) with seropositivity (Table 1). Those persons living in a shelter were seven times more likely to be infected (OR = 7.7, 95% CI = 3.0–20.0), while those who had traveled to a northeastern HIV hyperendemic area within the previous 2 years were five times more likely to be seropositive (OR = 5.2, CI 1.8–15.4). Finally, homosexual/bisexual males who were sexually active in the 6 months prior to the interview were 11 times more likely to be HIV positive (OR = 11.2, CI = 2.9–43.9).

Discussion

Our results are generally similar to previous research in low seroprevalence areas.[6–9] The widespread practice of AIDS-related risk behaviors in this midwestern locale provides the potential for higher infection rates in the future. At present, however, variables typically associated with HIV infection in high seroprevalence areas, such as race and ethnicity, use of shooting galleries, and frequency of injection had little predictive power, although many results are in the expected direction. In contrast with previous studies,[10–11] Whites and Blacks were about equally likely to be seropositive.

While our analyses are based on a small number of seropositive cases and should be interpreted cautiously, several new findings emerged. The results encourage some speculation about the movement of HIV to low seroprevalence areas as well as the key mechanisms for local dispersion. The significant relationship between travel to northeastern hyperendemic areas and HIV seropositivity is a new finding among IVDUs in low seroprevalence areas.

This study seems to support the findings of Battjes and colleagues[6] that homosexual/bisexual male IVDUs form a potential route for transmission of the HIV from non-drug-using gay males to heterosexual IVDUs in low seroprevalence areas. Our data emphasize the importance of travel as an additional mechanism for importing the virus into low seroprevalence areas. If the diffusion factors of mobility and homosexual/bisexual behavior are interrelated, future increases in the prevalence of HIV in currently low seroprevalence regions may be expected, given the high levels of risk behaviors. Such scenarios, tentative as they are, emphasize the critical need for preventive interventions in low seroprevalence areas.

Our results also suggest that homeless shelter residence is a potentially high-risk social setting that may serve as an additional indirect mechanism for the dispersion of HIV. While a high seroprevalence rate has been reported among male IVDUs residing in homeless shelters in New York City,[12] the association between shelter residence and seropositivity is a new finding for low seroprevalence areas and might contribute to understanding the natural history of HIV. Shelters bring together many of society's most vulnerable people, allowing intense social interaction. Given the current crack cocaine epidemic with its associated high-risk sexual behavior and disruption of social networks,[13–14] these interrelated processes are cause for concern.

Future research should examine IVDU mobility, homosexual/bisexual behavior, and social networks particularly as these interface with homeless shelter residence patterns. Focus should be directed toward understanding these factors within and between low and high seroprevalence regions. □

Frequency and Thoroughness of STD/HIV Risk Assessment by Physicians in a High-Risk Metropolitan Area

Bradley O. Boekeloo, PhD, ScM, Eric S. Marx, MTS, Alex H. Kral, BA, Steven C. Coughlin, PhD, Marjorie Bowman, MD, MPA, and David L. Rabin, MD, MPH

ABSTRACT

The US Preventive Services Task Force recommends that all primary care physicians assess the sexually transmitted disease/human immunodeficiency virus (STD/HIV) risk of all adolescent and adult patients. To determine whether factors amenable to change through continuing medical education are associated with frequent and thorough STD/HIV risk assessment, a telephone survey of primary care physicians in the Washington, DC metropolitan area was conducted (n = 961). Thirty-seven percent of physicians reported regularly asking new adult patients about their sexual practices; 60% asked new adolescent patients. STD/HIV risk questioning was associated with physicians' confidence in their ability to help prevent HIV, comfort with discussing patients' sexual practices, and perception of a large STD/HIV problem in their practice. These findings suggest that continuing medical education should target improvement in physicians' sexual practice questioning skills. (*Am J Public Health.* 1991;81:1645–1648)

Introduction

Because of recent increases in the number and incidence of sexually transmitted diseases (STDs) and the lethality of human immunodeficiency virus (HIV) infection, improved physician STD/HIV prevention practice is urgent.[1,2] The US Preventive Services Task Force recommends that all primary care clinicians obtain a complete sexual practice and drug-use history from all adolescent and adult patients.[1] Primary care physicians report however, that they infrequently assess the sexual practices of their patients.[3]

Recent studies indicate that discomfort with homosexuality is a barrier to HIV-related care.[3–5] Non-internist, older, male, solo-practice physicians and physicians having no AIDS patients are all reported to have less HIV-related competence.[3–5] Although many barriers to STD/HIV risk assessment cannot be overcome through continuing medical education (CME) (i.e., physician's age or type of practice), CME can potentially decrease barriers caused by lack of knowledge, predisposing attitudes, and skills. In this study, current levels of self-reported primary care physician STD/HIV risk questioning are measured and educationally mutable factors associated with this questioning are identified.

Methods

Baseline data for a demonstration project of physician office-based STD/HIV prevention programs using simulated patients[6] were obtained through telephone interview. The sampling frame was the 1988 American Medical Association (AMA) list of office-based practicing physicians whose mailing addresses were in the Washington DC metropolitan statistical area.

Physicians were eligible for participation in the study if (1) they identified themselves at the time of the interview as being in one of four designated primary care specialties (internal medicine, family practice, general practice, and obstetrics/gynecology), and (2) they delivered at least 1 hour of primary care each week. The overall survey response rate was 60% (N = 961).

All telephone survey questions were closed-ended, with trained interviewers recording responses on precoded forms. In data analysis, variable associations were measured using Pearson product-moment correlation coefficients and forward stepwise multiple linear regression (PROC REG).[7]

Independent Variables

Study physicians were asked about their personal and practice characteristics. They were also asked to rate the magnitude of the STD/HIV problem in their practice. A battery of seven 5-point Likert scale questions (available from the authors) was used to measure physicians' confidence in their ability to assess risk and successfully counsel patients in the prevention of HIV infection (Cronbach alpha = 0.68, range = 7–35, mean = 25.0, SD = 5.00, median = 25). Physicians were also asked about their comfort level when discussing sexual practices with five different types of patients: single women, homosexual women, long-time married patients, homosexual men, and single men. The cronbach A among these items was 0.78. These 3-point item scores were

*This question was asked only about new patients whom the physician knew had more than one sexual partner in the last ten years.

totaled and divided by 5 to create an overall Discomfort Scale. For obstetricians/gynecologists the scale excluded questions regarding male patients and total scores were divided by 3. Because the Discomfort Scale scores were skewed, they were categorized into levels of high, moderate, and low discomfort.

Dependent Variables

Physician STD/HIV risk questioning, the major outcome variable, was measured by asking physicians how often they ask new patients during initial general health examinations about nine sexual STD/HIV risk factors on a 5-point scale (Never-Always) (Figure 1). A summative scale of these items formed the STD/HIV Risk Questioning Scale (SRQ) (Cronbach alpha = 0.85, range = 9–45, mean = 28.46, SD = 7.75, median = 28). Frequency of asking 12 different types of patients about their sexual practices or changes in sexual practices was also obtained (Figure 2) on a 5-point scale (Never-Always).

Results

Characteristics of the Study Population

Study physicians were predominantly White (72%), male (80%), board certified in their primary care specialty (74%), and graduates of US medical schools (76%). Their average age was 47 years (SD = 10.61) and 48% were in solo practice. Sixty-five percent had diagnosed an HIV-positive patient. Information from the AMA indicated small but significant differences between study participants and nonparticipants on two of five variables: gender and practice organization (i.e., solo, partnership, group).

Physician STD/HIV Risk Questioning

During initial general health examinations of new patients, the majority of physicians reported regularly ("always" or "often") asking about history of STDs (71%) (Figure 1). Fewer physicians reported regularly asking about other STD/HIV risk factors such as condom use (56%), sexual preference (50%), anal or oral sex (29%), or number of partners (27%).

The percentage of physicians who reported regularly questioning patients about sexual practices varied widely by patient type (Figure 2). Thirty-seven percent of primary care physicians reported regularly asking their new adult patients about their sexual practices; 60% asked their new adolescent patients. The majority of physicians reported regularly asking about sexual practices of patients in traditional HIV risk groups—homosexual men (87%) and IV drug users (81%)—and patients who asked them about AIDS (92%).

Associations with STD/HIV Risk Questioning

SRQ scores were positively associated with several "immutable" characteristics of physicians and their practices in bivariate and multivariate analyses (Table 1) including being a foreign medical school graduate ($r = .12$, $p \leq .0002$), being female ($r = .12$, $p \leq .0003$), and having had four or more HIV-positive patients ($r = .10$, $p \leq .002$).

SRQ scores were also positively associated with "potentially mutable" characteristics of physicians in bivariate and multivariate analyses (Table 1) including perceiving STD/HIV infection to be a big problem in one's practice ($r = .23$, $p \leq .0001$), being comfortable when discussing sexual practices with patients ($r = .24$, $p \leq .0001$), and having greater STD/HIV prevention confidence ($r = .29$, $p \leq .0001$).

Discussion

This study indicates that in one of the highest STD/HIV incidence areas in the country, metropolitan Washington, DC, primary care physician STD/HIV risk assessment rates are slightly higher than those recently reported in other high-risk urban areas for Los Angeles,[8,9] but are well

[c]Unstandardized regression coefficient

below the rates called for by the Public Health Service's Year 2000 objectives.[2] Although the majority of physicians reported regularly asking new patients about their history of STDs during initial general health examinations, less than half of physicians regularly asked about sexual preference, and less than one third of physicians regularly asked about anal or oral sexual practices or number of sexual partners. These risk assessment rates may even be inflated given that physician self-reported practice has been observed to be greater than observed practice.[9-11]

Whether or not a physician reported asking patients about their sexual practices varied widely by patient type. While a majority of study physicians reported regularly asking about the sexual practices of patients in traditional HIV risk groups—homosexual or bisexual men and IV drug users—they infrequently reported regularly assessing the sexual practices of other patients, including single men and women. Therefore, many physicians reported obtaining information about sexual practices only if they already knew a patient was in a high-risk group. If the patient does not bring up the topic of AIDS[12] or his or her high risk STD/HIV status, it appears unlikely that the physician will address the patient's sexual risk of STD/HIV infection.

Three educationally immutable variables were weakly associated with more STD/HIV risk questioning in this study: being a female physician, having cared for four or more HIV-positive patients, and being a foreign-trained physician. These associations are not particularly useful in designing effective CME programs. Three educationally mutable variables were more strongly associated with STD/HIV risk questioning: physician perception that STD/HIV is a big problem in their practice; physician comfort with discussing various

patients', not just homosexual patients',[3] sexual practices; and physician HIV prevention confidence. These potentially mutable factors suggest mechanisms through which physician practice can be improved. Experiential training in sexual questioning[13] may provide physicians with exposure to and skills for assessing patients' personal risk behavior. Such training may decrease feelings of discomfort, increase perceptions about the magnitude of the STD/HIV problem in ones' practice, and increase HIV prevention confidence when discussing patients' sexual practices. At the least, such training may help physicians appropriately handle these barriers. Hence, this study suggests that experiential training for discussing patients' sexual practices may be important in increasing physician STD/HIV risk assessment of all patients. □

Changes in AIDS Case Reporting after Hospital Site Visits

Daniel Fife, MD, James McAnaney, and M. Abid Rahman, PhD

ABSTRACT

In an effort to improve AIDS case reporting, site visits (meetings with hospital staff to encourage reporting) were made to all Philadelphia hospitals. Comparisons of hospitals visited during a 7-week period with hospitals not visited during that period indicated that the site visits were followed by a marked increase in case reports. No similar increase was observed at the comparison hospitals. The increased reporting was accompanied by an increased lag time from diagnosis to report, suggesting that the additional reports at visited hospitals were the result of the identification of previously missed cases rather than a speedup of reporting. Cases reported after the visits were more likely to have white-collar occupations or private medical insurance than were those reported before the visits. (*Am J Public Health.* 1991;81:1648–1650)

Introduction

It is well documented that acquired immunodeficiency syndrome (AIDS) case reporting is incomplete,[1–3] and that many unreported cases can be identified through reviews of death certificates,[4–7] hospital discharge records,[8–10] and outpatient records.[11] In Oregon, a state with relatively few AIDS cases, Modesett recently demonstrated that AIDS case reporting was improved by reminders to hospitals and physicians in addition to reviews of hospital discharges and death certificates.[12]

We sought to determine whether reminders to hospitals also improved AIDS case reporting in a large city with many AIDS cases, and (if such reminders increased AIDS case reporting) to determine whether they did so by bringing to immediate attention cases that might otherwise have been reported in the future or by bringing to attention cases that were previously missed. We differentiated between these two possibilities by examining the lag time from diagnosis to report. In the first situation the lag time should decrease after the reminders (because cases were being reported sooner rather than later). In the second situation the lag time should remain constant or increase (because a new population of cases or a backlog of unreported cases was coming to light).

Methods

In August 1989, Philadelphia's commissioner of health wrote to each of the city's 46 hospitals requesting that the

administrator meet with Department of Health (DOH) staff to review and improve AIDS case-finding procedures. All hospitals were visited between September 1989 and March 1990, the schedule being determined by the availability of the relevant hospital staff (the administrator and the infection control director). During the 7 weeks beginning January 8, 1990, 21 hospitals were visited. For the present study, these 21 hospitals were considered study hospitals. To provide a comparison hospital for each study hospital, the study hospitals were ordered according to the previous year's number of reported AIDS cases. The remaining Philadelphia hospitals were ordered similarly. A comparison hospital was assigned to each study hospital by pairing the ordered lists.

Reports from each study and comparison hospital pair were grouped by week of receipt relative to the date of the visit to the study hospital. The numbers of reports during the 6 weeks before the visit and the 6 weeks after the visit were compared using a chi-square test, and the mean lag times from diagnosis to report were compared using an unpaired t test (Table 1). Philadelphia collects data on the medical insurance, occupation, and employment status of each reported AIDS case. Medical insurance was grouped as private (Blue Cross, etc.), public (Medicaid, etc.), unknown, or none. Occupation was grouped as white-collar (professional, clerical, etc.) or blue-collar (crafts, labor, etc.).

Visits by DOH staff lasted 30 to 60 minutes and involved a brief discussion of the importance of AIDS case reporting, a detailed review of the hospital's case identification and reporting procedures, and a review of the annual number of reports from that hospital and the mean lag time for those reports. Any problems that were identified were discussed. Most of these discussions led to mutually agreeable changes. The visitors showed maps tracing the increase of AIDS in Philadelphia, distributed pocket cards summarizing the diagnostic criteria for AIDS, thanked the hospital staff for their work so far and for taking the time to meet, and offered to provide feedback on future reporting through lists or summary statistics.

Results

After the visits, the number of case reports increased at the study hospitals and decreased at the comparison hospitals. The proportion of reports coming from the study hospitals increased significantly. The mean lag time for reports from the study hospitals increased significantly. The mean lag time for reports from the comparison hospitals did not increase (Table 1). The increase in the number of reports from the study hospitals began slightly before the site visits (Figure 1).

Comparisons of the cases reported during the 6 weeks before the visit and those reported during the 6 weeks after the visit revealed that, at the study hospitals, there were significant increases in the proportion with white-collar occupations (4/27 [15%] vs 19/48 [41%]; $P < .05$) and private medical insurance (10/33 [30%] vs 26/48 [54%]; $P < .05$). However, at the comparison hospitals there was little change in the proportion with white-collar occupations (4/23 [17%] vs 3/16 [19%]; $P > .05$) or private medical insurance (5/23 [22%] vs 3/16 [19%]; $P > .05$). At both the study and comparison hospitals there were nonsignificant increases in the proportion of cases that reported homosexual contacts and the proportion who were White, and no significant changes in the proportion by gender.

Discussion

The present study provides evidence that hospital site visits are an effective way to increase AIDS case reporting in an urban area with high AIDS rates, and that the additional reports do not simply reflect earlier notification of cases that would have been reported later. The increase in the number of reports from the hospitals

appeared to begin slightly before the site visits. Visits were scheduled several weeks in advance, and it is possible that case finding received additional attention in anticipation of the visit.

The differences in occupation and insurance status between the cases reported before the visits and those reported afterward suggest that it is more difficult to identify AIDS patients with white-collar occupations and private insurance than those in other groups. This possibility deserves further investigation. If AIDS case reporting is biased, with underascertainment of those who are employed in white-collar occupations or have private medical insurance, then current statistics based on reported AIDS cases will overestimate the extent to which AIDS cases are concentrated among socially marginal groups and underestimate the extent to which they occur in other groups.

Relatively little is known about the reasons why cases fail to be reported. In the course of our visits, several administrators commented that we appeared to be marketing case reporting. From that perspective, we could summarize the present study by saying that hospital site visits are an effective way to impress the idea that case reporting deserves space on the medical caregiver's crowded priority list. □

Patterns of Breast and Cervical Cancer Screening at Three Public Health Centers in an Inner-City Urban Area

Steven Whitman, PhD, David Ansell, MD, Loretta Lacey, RN, DrPH, Edwin H. Chen, PhD, Nyambi Ebie, MD, Jade Dell, MA, and Clyde W. Phillips, MD

ABSTRACT

In an effort to examine breast and cervical cancer screening patterns among poor African-American urban women, medical records were abstracted at three public health centers located in the inner city of Chicago. The proportions of eligible women at these three centers who received Pap smears, breast examinations, and mammograms were computed. These proportions were notably low and differed significantly among the three centers. Because the literature is now suggesting that an appropriate sequence best defines adequate screening, sequences of screenings were also determined and were found to be lacking. All of these screening histories fall far below the screening objectives set by the National Cancer Institute for the year 2000. This information suggests that interventions are needed that will help health centers serving poor women to deliver more frequent cancer screening.(*Am J Public Health.* 1991;81:1651–1653)

Introduction

African-American women have a higher incidence of cervical cancer and higher mortality rates and lower survival rates than White women.[1] Furthermore, although White women have a higher incidence of breast cancer, the prognosis for African-American women is worse. For example, the ratio of breast cancer mortality to incidence is higher for African-American women (38%) than for White women (32%). Five-year survival rates (63% vs 75%) demonstrate a similar difference.[2] These differences appear to be due in large part to the fact that African-American women with breast cancer are diagnosed at a considerably later stage, even when relevant variables are stratified.[3,4] Such racial differences are particularly troublesome because it now is generally accepted that appropriate screening can reduce mortality from breast and cervical cancer.[5–8]

There are only a few published reports documenting breast and cervical cancer screening patterns in the United States. We have not been able to locate any study that presents specific information on screening patterns for poor urban African-American women. To present such information is our purpose in this paper. We use data from Chicago Department of Health centers to derive the percentages of women who receive Pap smears, breast examinations, and mammograms for selected time intervals and sequences of screens. We then compare our findings with those in the literature and discuss the policy implications that result from this comparison.

Methods

Setting

The data were taken from three public health centers located on the south side of Chicago in very poor neighborhoods consisting almost entirely of African-American people. Virtually all of the patients attending these centers are African-American and about 75% are female.

Data Collection

We abstracted data from medical records to examine the screening histories of African-American women who attended these clinics between February and April 1989. A code manual and code sheet were produced for this purpose and thoroughly pretested. Charts were abstracted for all eligible African-American women who had made an appointment (even if it was not kept) or who walked in and were seen (even if there was no appointment) during the clinic session prior to coding.

The definitions of eligibility, for the purposes of this study, were as follows:

Pap smear	age 40 or over with no hysterectomy
Breast examination	age 40 or over
Mammogram	age 50 or over

Each chart that was reviewed could thus contain information about a woman eligible for no screens, one screen, two screens, or three screens. We were interested not only in when a woman had received her last screening examination, but in what the sequence of screens had been.

TABLE 1—Percentage of Eligible African-American Women Who Received Screening Examinations at Three Health Centers (A,B,C), by Interval of Screening (ns in parentheses)

Interval, y	Center			Significance[a]		
	A	B	C	A,B	A,C	B,C
			Pap smear			
1	12 (284)	39 (189)	33 (211)	<.001	<.001	NS
2	23 (263)	68 (168)	68 (209)	<.001	<.001	NS
5	59 (189)	81 (115)	83 (159)	<.001	<.001	NS
10	81 (74)	84 (56)		NS	—	—
			Breast examination			
1	6 (454)	36 (352)	12 (369)	<.001	<.005	<.001
2	13 (415)	71 (311)	40 (367)	<.001	<.001	<.001
5	40 (290)	84 (212)	72 (272)	<.001	<.001	<.005
10	76 (121)	87 (101)		<.05	—	—
			Mammogram			
1	3 (394)	17 (303)	24 (337)	<.001	<.001	<.05
2	6 (367)	32 (269)	46 (336)	<.001	<.001	<.001
5	12 (262)	54 (189)	60 (257)	<.001	<.001	NS
10	12 (113)	48 (91)		<.001	—	—

Note. Eligible women were defined as follows: for Pap smear, age 40 or over, with no hysterectomy; for breast examination, age 40 or over; for mammogram, age 50 or over.
[a]NS = not significant.

TABLE 2—Percentage of Eligible African-American Women Who Received Screening Examinations at Three Health Centers (A,B,C), by Number Received within Previous 5 Years

Number of Exams	Center			Significance[a]		
	A	B	C	A,B	A,C	B,C
	Pap Smear					
	(n = 192)	(n = 141)	(n = 163)			
<2	72	29	47			
2	12	20	22			
>2	16	51	31	<.001	<.001	<.005
	Breast Examination					
	(n = 291)	(n = 211)	(n = 272)			
<2	87	37	64			
2	7	26	24			
>2	6	37	12	<.001	<.001	<.001
	Mammogram					
	(n = 262)	(n = 188)	(n = 257)			
<2	98	84	77			
2	2	12	16			
>2	<1	4	7	<.001	<.001	NS

Note. Eligible women were defined as follows: for Pap smear, age 40 or over, with no hysterectomy; for breast examination, age 40 or over; for mammogram, age 50 or over.
[a]Significance results were computed only for percentages for >2 screens. NS = not significant.

We therefore abstracted data for the previous 10 years at Centers A and B, and the previous 5 years at Center C depending on how long the woman had been attending the clinic. Coding was conducted for 6 days at each of the centers. Sample sizes for Pap smears are smaller than for breast examinations or mammograms because so many women (over 40%) at these centers had had a hysterectomy.

Data Analysis

All analyses are based on comparisons of proportions of women screened. A two-tailed *t* test of proportions was used, along with a significance level of 5%.

Results

Table 1 presents the percentage of women screened at each of the three centers and the corresponding sample sizes. Only 12% of eligible women at Center A had received a Pap smear within the previous year, compared with 39% at Center B and 33% at Center C. The percentages for Centers B and C do not significantly differ ($P > .05$), but both centers performed a significantly larger percentage of Pap smears ($P < .001$) than Center A. Percentages of women who had had a Pap smear within the previous 2 years, 5 years, and 10 years are also shown in Table 1, along with the corresponding significance results. About 18% of the women at Centers A and B had not had a Pap smear within the past 10 years. Table 1 also presents results for breast examinations and mammograms. The patterns for these two screening procedures are similar to those for Pap smears.

We also analyzed the sequence of screening. Table 2 shows the percentage of women who had been attending these clinics for at least 5 years and who had had fewer than two, two, and more than two Pap smears, breast examinations, and mammograms during the previous 5 years. Most recommendations for these procedures for women in these age groups suggest annual screening.[9-11] Thus, let us conservatively define "appropriate screening" as more than two screens in the past 5 years. Using such a definition, only 16% of the women at Center A were being appropriately screened for cervical cancer, compared with 51% at Center B

and 31% at Center C. As indicated in Table 2, all of these percentages differ significantly from one another. Similar patterns exist for breast examinations and mammograms, also presented in Table 2.

TABLE 3—Average Number of Visits per Year by Eligible African-American Women to Three Health Centers

	Center A	Center B	Center C
Average number of visits	35.6	35.7	26.9
Average number of years attending	7.1	7.2	7.5
Average number of visits per year	5.0	5.0	3.6

Note. Eligible women were defined as follows: for Pap smear, age 40 or over, with no hysterectomy; for breast examination, age 40 or over; for mammogram, age 50 or over.

Discussion

Most of the observed differences in the percentages of eligible women receiving a screen in a given interval or a sequence of screens in a given interval are statistically significant. Although we performed many significance tests, thus somewhat altering the true significance levels of the tests, the trends are unmistakable. Center A was screening women at a far lower rate than Centers B and C; to a lesser extent, Center C was doing significantly worse than Center B. We do not yet have an adequate explanation for such differences.

In order to try to understand the causes of these differences, we examined the demographic characteristics of the clinics. In another study, we found that the women served by Centers A and B were remarkably well matched on virtually all demographic characteristics, as well as on factors related to knowledge and attitudes.[12] Center C was not part of the latter investigation, but we know from unpublished data that the women served by this Center are demographically well matched with the women served by Centers A and B.

There is now some excellent literature, almost all of it from Europe, that suggests that the hallmark of good screening is a sequence of multiple negative tests within a "short interval."[6,8,13] Much of this literature is methodologically sound and presents convincing evidence that effective screening depends on such a sequence. Unfortunately, these studies present varying results with respect to what this optimal number may be and how long this "short interval" is. We can see from Table 2 that a very large percentage of the women at these centers are not receiving "appropriate" cancer screening for cervical cancer, when this definition is based on a standard of more than two screens in 5 years. The results are even more sobering for breast examinations and mammograms.

These results take on additional importance in light of the average number of clinic visits for the women in our sample (Table 3). The women attending Centers A and B averaged 5 visits per year, while the women attending Center C averaged 3.6 visits per year. These women have frequent access to health care resources, yet still do not receive adequate cancer screening.

The National Cancer Institute has set as a goal for the year 2000 that 80% to 90% of women will have Pap smears every 3 years and that 80% of women between the ages of 50 and 70 will receive annual breast examinations and mammograms.[14] The data presented in Tables 1 and 2 suggest that these goals are not even being approximated for the women attending the health centers in our study.

To our knowledge, this is the first study that presents an image of breast and cervical cancer screening derived from medical records for poor African-American women who most need cancer screening.[15,16] It also appears to be the first study from the United States that presents sequences of such screenings. Based on these findings, we conclude that the women in our sample, all of whom were attending public sector clinics, are not receiving appropriate cancer screening. This is a situation that demands remediation. □

The Impact of Vitamin A Supplementation on Morbidity: A Randomized Community Intervention Trial

Mutee H. Abdeljaber, MD, DrPH, Arnold S. Monto, MD, Robert L. Tilden, PhD, M. Anthony Schork, PhD, and Ignatius Tarwotjo, PhD

ABSTRACT

A randomized community trial investigated the impact of vitamin A supplementation on symptoms of respiratory and enteric infections among Indonesian children aged 1 to 5 years. A sample of 450 villages had been randomized into 229 villages that received vitamin A distribution and 221 that were observed as controls. The prevalence rates of cough, fever, and diarrhea were reduced in the treatment villages compared with the control villages by 8%, 5%, and 11%, respectively, but the reduction was not statistically significant. These results indicate that vitamin A supplements did not produce a substantial reduction in these symptoms, in spite of a reported reduction in all-cause mortality. (*Am J Public Health.* 1991;81:1654–1656)

Introduction

Many have hypothesized that vitamin A deficiency plays a major role in mortality and morbidity from respiratory and enteric infections.[1–5] In an Indonesian study, preschool children with vitamin A deficiency (measured by xerophthalmia) were at a twofold higher risk of developing respiratory tract infections and a threefold higher risk of developing diarrhea than their peers without xerophthalmia.[6] An Indian study reported that children with mild xerophthalmia were again at a twofold risk of developing respiratory tract infections, but were not at greater risk of developing diarrhea than controls.[7] In a later Indonesian study, vitamin A supplements twice a year reduced mortality by 34% in the treated group compared with controls, but the impact of the supplements on morbidity has never been analyzed.[8] The current study performs such an analysis, examining the effect of vitamin A supplementation in reducing the frequency of symptoms of respiratory and enteric infections.

Methods

The data had been collected by the Aceh study group, in Aceh province at the northern tip of Sumatra, Indonesia, to investigate the impact of vitamin A supplements on xerophthalmia, mortality, and growth.[8,9] The Aceh study consisted of a sample of 450 villages, randomized into 229 villages (15 101 resident children aged 1 to 5 years), that received vitamin A distribution and 221 villages (13 760 resident children) that were observed as controls. Each village in the two groups was visited twice, first for the baseline survey and second for the follow-up survey 1 year later. Capsules of vitamin A, containing 200 000 international units were distributed by a trained volunteer to preschool children in the treatment villages at the time of the first visit and 6 months later.

The first survey was conducted between September 1982 and August 1983, by a trained team consisting of an ophthalmologist and five enumerators. Households having children under 60 months of age were identified and asked about history of their having cough and fever, and diarrhea, in the previous week. Cough and fever that occurred and lasted for at least 24 hours in the previous week were used to indicate respiratory infection. Diarrhea, defined as having loose or watery stools for four or more times per day in the previous week, was used to indicate enteric infection. At baseline, socioeconomic data were collected concerning paternal age, education, and occupation, as well as house sanitation and source of drinking water. Children were examined for xerophthalmia according to standard criteria.[10] Follow-up visits were made 9 to 13 months after the baseline. The same team visited each village, reexamined the children's eyes, and recorded the number of deaths and the occurrence of diarrhea, cough, and fever during the previous week. Since randomization was carried out on the village level, data were aggregated by village (means and percentages of the appropriate population), instead of by child.

This paper was submitted to the journal July 12, 1990, and accepted with revisions April 24, 1991.

Results

Table 1 shows that the two groups of villages were comparable in baseline prevalence of cough, fever, diarrhea, and xerophthalmia ($P > .05$). The two groups were also comparable for other baseline demographic and socioeconomic variables that might be related to the transmission of infections. The age and sex distribution of children and the village size in the two groups were similar.[8,9] Table 2 shows the prevalence rates of cough, fever, and diarrhea in the two study groups before and after vitamin A intervention. Data for the two surveys were collected at the same time of the year by the same team, whose members received standardized training. There was an unexpected reduction in the postintervention prevalence rates in the two study groups compared with the preintervention rates. Postintervention prevalence of cough and fever in the treatment group was 17.0 and 25.0 cases per 100 children, compared with 18.6 and 26.7 cases per 100 children in the control group. Thus, the risk difference was 1.6 per 100 children for cough (95% confidence interval [CI] = −5.7 to 8.9) and 1.7 per 100 children for fever (95% CI = −6.6 to 9.9), and the percentage reduction in the point prevalence in the intervention group was 8.6% for cough and 6.4% for fever. These differences were very small and statistically insignificant ($P > .05$). The prevalence of diarrhea in the intervention group was 4.0 cases per 100 children at the follow-up survey compared with 4.5 cases per 100 children in the control group. The risk difference between the two groups was 0.5 case per 100 children (95% CI = −4.2 to 5.2). The percentage reduction in diarrheal rates in the treatment group was 11.1%, as compared with the control group.

TABLE 1—Comparison of Baseline Characteristics between the Two Groups of Villages: Controls and Treatment

Characteristics	Control (209 villages)	Treatment (219 villages)	*P* Value[a]
Baseline prevalence of symptoms (cases/100 children)			
Cough	31.7	31.7	.97
Fever	46.1	46.2	.96
Diarrhea	7.5	7.4	.90
Xerophthalmia (cases/100 children)	2.30	3.40	.09
Mother's age (mean %)			
<20	3.00	3.50	.75
21–30	48.00	48.00	.68
31–40	35.00	36.00	.48
41–50	11.00	11.00	.48
50+	3.00	1.50	.15
Education			
6 years	82.00	83.00	.42

TABLE 2—Prevalence Rates of Diarrhea, Cough, and Fever before and after Vitamin A Treatment (No. of cases per 100 children) in the Aceh Clinical Trial Study

	Control Group (n = 209)		Treatment Group (n = 219)	
Symptoms of Infection	Pre-treatment	Post-treatment	Pre-treatment	Post-treatment
Cough	31.7	18.6	31.7	17.0
Fever	46.1	26.7	46.2	25.0
Diarrhea	7.5	4.5	7.4	4.0

Discussion

Mortality analysis, using the Indonesian Aceh study, showed that vitamin A supplements to preschool children with marginal vitamin A deficiency reduced mortality by 34%.[8] The present analysis examined the impact of vitamin A supplements on morbidity in terms of cough, fever, and diarrhea. Morbidity should be a more direct outcome of marginal vitamin A deficiency than mortality, which is the outcome of complex health-related variables.[11,12] However, the results demonstrated a statistically insignificant reduction in the rates of cough, fever, and diarrhea.

While the vitamin A intervention did not produce significant differences in morbidity, socioenvironmental factors such as sanitation, water supply, and season were significantly related to these outcomes.[13] This indicates that even though data were aggregated by village, which could potentially attenuate associations, these differences could still be detected.[14] A variety of explanations can be offered for finding, in the same data, a major vitamin A effect on mortality but not on symptoms of the two leading causes of childhood death—respiratory and enteric infections. It is possible that the effect of vitamin A intervention may be on case fatality, with no decrease in frequency and duration of symptoms of respiratory and enteric diseases. In the Philippines, the findings of Tupasi et al., who reported that low socioeconomic status was associated with morbidity and overall malnutrition was associated with mortality, might support this hypothesis.[15] In any event, the current analysis indicates that large-dose vitamin A supplementation is unlikely to produce a rapid and dramatic effect on respiratory and enteric morbidity in the absence of changes in overall malnutrition and socioenvironmental factors. Research currently in progress should clarify the relationship between vitamin A deficiency and mortality and determine whether

these results can be replicated in settings with different socioenvironmental risk factors. □

Occupational Injuries and Illnesses among Washington State Agricultural Workers

Paul Demers, MS, and Linda Rosenstock, MD, MPH

ABSTRACT

In Washington state 29 451 workers' compensation claims were filed by farm workers between 1982 and 1986. Five percent of claimants were under 18 years of age, including 1.3% under the age of 16. Agricultural workers were found to be at higher risk than other workers in the state for fatal injury (relative risk [RR] = 2.5, 95% confidence interval [CI] = 1.7–3.7), sprains and strains (RR = 1.4, CI = 1.3–1.4), fractures (RR = 2.3, CI = 2.2–2.4), dislocations (RR = 1.9, CI = 1.7–2.2), concussions (RR = 1.9, CI = 1.6–2.3), amputations (RR = 2.5, CI = 2.0–3.1), dermatitis (RR = 4.3, CI = 4.0–4.7), systemic poisoning (RR = 3.4, CI = 3.1–3.7), respiratory disease (RR = 1.7, CI = 1.0–2.9), and tendonitis (RR = 1.2, CI = 1.1–1.4). (*Am J Public Health.* 1991;81:1656–1658)

Introduction

Agricultural employment is among the nation's most hazardous occupations.[1,2] Farm workers have been noted to be at increased risk for musculoskeletal disorders, noise-induced hearing loss, dermatitis, respiratory diseases, and cancer.[1,3–5] The most widely recognized hazards of farm work are pesticides and agricultural machinery, but farm workers are also exposed to severe climatic conditions, physical fatigue and stress, parasites, infectious diseases, toxic plants, and chemicals needed to maintain farm machinery.[5,6]

We reviewed workers' compensation claim data for farm workers in the state of Washington between 1982 and 1986 in order to characterize the nature of work-related illnesses and injuries among farm workers and compare their rates to those of nonagricultural workers.

Methods

The state supplied the investigators with computer tapes containing data on all claims filed in Washington between January 1, 1982, and December 31, 1986. The nature and source of injury and illness claims were derived from the first report received at the time the claim was filed, and claim status was determined as of April 1988. Using hours submitted to the state by employers for billing purposes, the number of full-time equivalent (FTE) agricultural workers was estimated. In or-

Rejected	1732
Total	29 451

*Kept on salary, loss of earning power, or no decision as of the time the data were generated.

der to calculate rates for nonagricultural workers, data from the state employment security commission were used. Relative risks were calculated by comparing the rate for agricultural workers to the rate for all other workers in the state. Confidence intervals were calculated using Taylor series methods.[7]

Results

A total of 29 451 claims were filed by farm workers between 1982 and 1986. The status of all claims as of 1988 is given in Table 1. Table 2 shows the number of accepted claims by the type of injury or illness. The claims rate for agricultural workers was almost 50% higher than for nonagricultural workers, with substantial excesses for each of the categories examined except hearing loss (Table 3).

Between 1982 and 1986 only 53 claims were filed for organophosphate pesticide (OP) related illnesses, with 11 (21%) rejected and only 3 (6%) resulting in compensable time loss. Of the 54 claims filed for pesticides other than organophosphates, 9 (17%) were rejected and only 3 (6%) resulted in compensable time loss. During the study period there were 148 dermatitis claims, and 106 systemic poisoning claims were attributed to "other and unspecified chemicals."

Although 74% of all claimants were between the ages of 18 and 40, 5% were under 18 years of age and 1.3% were under 16. Ninety-four percent of these claims were accepted and 20% had compensable time loss. One claim was accepted for a childhood fatality: a 15-year-old orchard worker died from multiple injuries following a work-related motorcycle accident. Other serious injuries for which claims were accepted for children included 7 amputations, 90 fractures, 11 dislocations, and 8 concussions. These serious injuries represented 8.8% of all claims accepted for children vs 7.1% of all claims filed by adults.

Discussion

We found agricultural workers in the state of Washington to be at higher risk than other workers for both occupational injuries and illnesses. Approximately 5% of the claims examined by this study were filed for children. It is not possible to determine if the higher proportion of serious injuries seen in children compared to adult farm workers was because children are at higher risk or because claims were not filed for less serious injuries. Because of the serious nature of many of these claims, this population should receive special attention by regulatory and health agencies.[8]

We were able to identify relatively few pesticide related claims. This may be due to a lower than anticipated risk or to inaccurate or underreporting. In analyses of California pesticide-related illnesses, Kahn[9] and Blanc et al.[10] found that only a small fraction of cases were reported despite the fact that physicians are required to report pesticide poisonings in that state. A survey of farm workers in Washington State found that only 8% to 15% of those who felt ill after exposure to pesticides sought medical attention.[11] In addition, the relatively large number of claims attributable to other and unspecified chemicals points to the need for better reporting by physicians and more detailed coding by the responsible state agency. The recent enactment of legislation making pesticide poisonings reportable in Washington may provide a better means of surveillance in the future.

This study suffers from an inherent limitation: compensation records are known to be insensitive to the total extent of occupational disease.[9,10,12–14] Despite this limitation, recent investigations have found that internal analyses of compensation data appear to be valid.[15,16] Moreover, in the case of farm workers few other sources of data are available. An additional limitation was the lack of reliable estimates of the number of farm workers in the state during the study period. One advantage of using workers' compensation data is that they are based on hours and allow the calculation of FTE workers. Because of the seasonal nature of farm labor, the use of FTE workers rather than estimates made at one particular time during the year may better represent person-years at risk.

TABLE 2—Accepted Injury or Illness Claims: Washington State Farm Workers, 1982 to 1986

Injury or Illness	Accepted Claims	(%)
All injuries	25 097	(90.6)

Hearing loss	7	(<0.1)
Freezing	9	(<0.1)
Other illness	13	(<0.1)
Other, ill defined, or unknown	868	(3.1)
Total	27 719	(100)

The increased risk for agricultural workers compared to other workers could be explained by different reporting rather than a real difference between the two populations. This could occur if farm workers were more likely to submit claims or if their numbers are underestimated. Because some farm work is paid for on a piece rate rather than on an hourly basis, farm owners may sometimes be forced to calculate hours based on a formula using

TABLE 3—Comparison of Workers' Compensation Claims Rates between Agricultural and Nonagricultural Workers: Washington State, 1982 to 1986[a]

Type of Claim	Agricultural Workers Rate	Nonagricultural Workers Rate	Rate Ratio (95% Confidence Limits)
All accepted claims	207.84	139.76	1.49 (1.48–1.50)
Sprains and Strains	69.08	49.91	1.38 (1.35–1.41)
Fractures	12.41	5.35	2.32 (2.21–2.43)
Dislocations	1.39	0.73	1.91 (1.66–2.20)
Concussions	0.76	0.40	1.92 (1.59–2.32)
Amputations	0.59	0.23	2.53 (2.04–3.14)
Dermatitis	3.83	0.89	4.32 (3.96–4.71)
Systemic poisoning	3.89	1.15	3.39 (3.11–3.69)
Tendonitis	1.65	1.32	1.25 (1.10–1.42)
Hearing loss	0.05	0.29	0.16 (0.08–0.34)
Respiratory disease	0.09	0.05	1.69 (0.97–2.94)
Fatalities	0.19	0.08	2.50 (1.71–3.66)

[a]Rates per 1000 person years at risk.

the average number of bushels picked per hour or some other productivity estimate. While it is possible that this practice and the general difficulties of enforcing workers' compensation laws in agriculture could lead to some underreporting of hours, a bias in this direction would have to be extremely large to explain the magnitude of the observed differences for most of the outcomes, and substantial fines may be levied against an employer if a claim is filed and no workers' compensation premiums have been paid.

The analysis of workers' compensation claims submitted by farm workers in Washington State has provided a means to examine some aspects of work-related injuries and illnesses in this understudied population. The needs of farm workers should be prioritized for regulatory action and other forms of intervention. □

The Effects of Removing a Statutory Barrier to Workers' Compensation for Farm Workers

Paul Demers, MS, and Linda Rosenstock, MD, MPH

ABSTRACT

In 1983 the Washington State Supreme Court ruled unconstitutional a unique exemption that excluded farm workers from workers' compensation if they had not earned $150 in continuous work with the same employer. In order to examine the effect of removing this restriction, workers' compensation data were analyzed to examine the number of farm workers covered, the number of claims submitted, and claim acceptance rates before and after the ruling. Although the 1983 ruling appears to have had a significant impact on the treatment of claims, no increase in utilization of the workers' compensation system was observed. Further intervention is required if the objective of treating farm workers equitably is to be realized. (*Am J Public Health.* 1991;81:1659–1660)

Introduction

Differential treatment by government regulatory agencies has contributed to the plight of farm workers.[1–3] Even in cases where agencies have been mandated to treat farm workers equitably, enforcement is hampered by the lack of staff with training in farm hazards and fluency in Spanish, the seasonal nature of agriculture, and the difficulty in reaching widely scattered and often remote work places. Farm workers have also received differential treatment in regard to workers compensation, and many states still do not cover farm workers.[4] In Washington State prior to 1984, agricultural workers were exempted from coverage if they had not earned $150 in continuous employment with the same employer. Because of this exclusion, farm worker advocates estimate that at any time 20% to 40% of farm workers were ineligible for compensation because of the pattern of frequently changing and intermittent employment and the employers' awareness of this liability caveat. In September of 1983, 7 years after it was legally challenged, the Washington State Supreme Court ruled that the exemption was unconstitutional because it denied equal protection to farm workers by infringing on their right to travel. In October of that same year the state complied with this ruling and began universal coverage for farm workers.

The objective of this study was to explore the effect of the 1983 Washington State Supreme Court ruling expanding farm worker coverage under the state's compensation system.

Methods

The Washington (State) Department of Labor and Industries supplied the investigators with computer tapes containing data on all claims filed in Washington between January 1, 1982, and December 31, 1986. Workers' compensation coverage, utilization of the system, and treatment of farm worker claims were examined before and after the Washington State Supreme Court ruling. Using hours submitted to the state by agricultural employers for billing purposes, the number of full-time equivalent (FTE) agricultural workers was estimated in order to evaluate trends in the number of workers theoretically covered. Two occupational groups were used for comparison: farmers and farm managers (1980 US Census codes 473–477) and unskilled or semi-skilled blue collar workers (703–889).

Results

The number of FTE agricultural workers covered by the system based on premiums paid remained relatively stable during the 5-year period (Table 1). Approximately 2000 more agricultural workers were covered in 1984 than in 1983, a 7% increase. The number of both submitted and accepted farm worker claims peaked in 1983 and declined in each succeeding year. There were fewer claims filed in the last quarter of 1983 (1487) than in the same quarter of either the preceding (1604) or following (1644) years, indicating that the 1983 figures were not distorted by a flood of claims submitted following the Washington State Supreme Court ruling.

Table 2 presents the rejection rates for claims made by farm workers, farmers and farm supervisors, and unskilled blue collar workers insured by the workers' compensation state fund during the study period. The claim rejection rate for farm workers relative to unskilled blue collar workers was 1.69 in 1982 (95% confidence interval [CI] = 1.49–1.92) and 1.47 in 1983 (CI = 1.28–1.68), while the relative rate was 1.06 in 1984 (CI = 0.92–1.22) and

Unskilled blue collar workers	4.4	4.0	4.4	4.7	7.5

*All figures are percentages.

similar in succeeding years. Of note, the rejection rate for all groups increased dramatically in 1986.

Discussion

We found a substantial increase in the acceptance of claims filed by farm workers following a judicial ruling that resulted in the removal of a statutory restriction unique to workers in this sector. This increase suggests that the compensation caveat had been a critical factor in rejecting otherwise compensable claims. While this change in the administrative management of farm worker claims is likely the result, and certainly one of the intended benefits, of the Washington State Supreme Court ruling, the limited impact of the ruling on other aspects of workers' compensation is surprising. Unfortunately, although there are indications that coverage of farm workers—in the form of premiums paid by agricultural employers—may have increased slightly after the ruling, utilization of the system does not appear to have increased and indeed claim rates actually decreased in subsequent years.

These trends occurred in spite of the fact that after the ruling the Department of Labor and Industries issued press releases statewide informing all employers then paying premiums. In addition, substantial fines continue to be levied against an employer if a claim is filed and no workers' compensation premiums have been paid. It is possible that farm worker advocates overestimated the effect of the $150 exclusion in inhibiting the filing of claims, but there are many other potential barriers to workers' compensation that were not addressed by the ruling. These include the lack of knowledge of legal rights, of access to health care, of US citizenship, and fluency in the English language.

An inherent limitation of this study is the absence of reliable estimates of the number of farm workers in the state during the study period. Because the number of farm workers may fluctuate from year to year based on weather and market conditions, an independent indicator of the true number of farm workers would have been a useful benchmark against which to measure coverage based on premiums paid. Unfortunately, there is no agency that regularly collects this information. The state OSHA agency (WISHA) does make estimates of the workers in agricultural production on farms with 11 or more employees based on surveys of random samples of employers.[5,6] Using these data as a relative indicator of the true number of farm workers in the state, the ratio of workers' compensation to WISHA estimates was calculated. The ratio was 1.06 in 1982 vs 1.08 in 1986. These figures indicate that there was little difference between the two years in the way employers submitted hours for billing purposes.

If the state is to fulfill its commitment to treat farm workers in the same way as other workers, additional interventions are needed, including informing farm workers directly of their rights and protection under the law. □

Impairments Due to Injuries

Americans have approximately 19 million physical impairments that are due to injuries. Each year such impairments cause about 275 million days of restricted activity—days spent in bed, absent from work or school, or at less than normal functional capacity. In addition, almost half of these impairments cause a long-term reduction in functional capacity, such as an inability to continue to work or a reduction in the amount or kind of work.

These are some of the key findings from a recent National Center for Health Statistics (NCHS) report, *Selected Impairments Due to Injuries: United States, 1985–87.*[1] The report shows that large numbers of Americans are impaired by injury and that those impairments have a tremendous impact on the lives of individuals and the economy. It confirms recent research about the employment costs of impairments[2] and reinforces the conclusions of a report of the Institute of Medicine that injury is one of the principal public health problems facing America.[3]

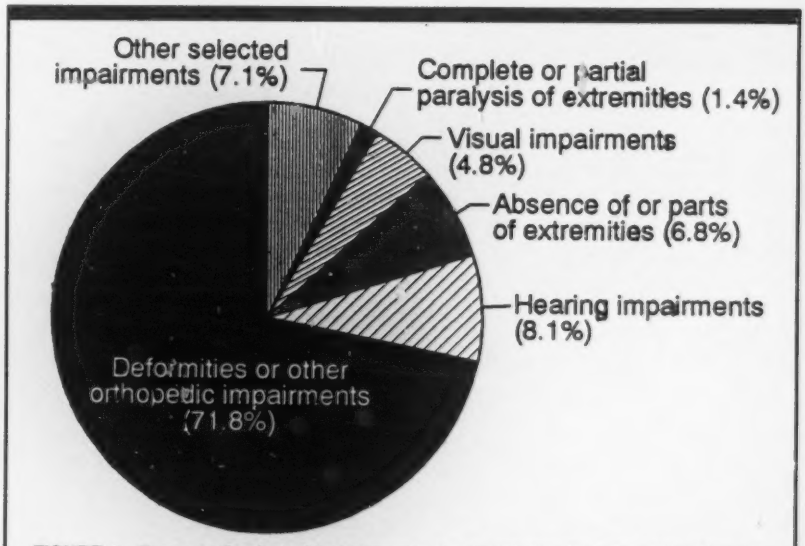
The data are from the 1985 to 1987 National Health Interview Survey (NHIS). All national estimates in this report represent annual averages over 3 years (1985 to 1987). The survey has been described[4,5] and the questionnaires have been published.[6] In brief, the NHIS is a continuing national survey of the health of the civilian, noninstitutionalized population of the United States based on an area probability sample. In 1985 to 1987, more than 106 000 households and 276 000 persons were included in this sample after a noninterview rate of 4.3% had been accounted for.

This report presents estimates of the number of impairments, which is larger than the number of people with impairments because a person can have more than one impairment due to injury. A physical impairment is defined as a chronic or permanent defect, usually static in nature, which represents a decrease in or loss of ability to perform various functions. Regardless of the date of onset, impairments due to injuries were categorized as chronic conditions in the NHIS and then were further classified by means of a special supplementary code according to the type of functional impairment and etiology (the classification can be found in the NCHS Medical Coding Manual).[7]

During the mid-1980s, the 236 million people in the civilian, noninstitutionalized population had 71 million impairments. About 26% of these impairments were due to injuries. Of the 19 million impairments caused by injuries, about 12% resulted from injuries that occurred in the 12 months prior to the interview.

Figure 1 shows the types of impairments caused by injuries. Deformities or orthopedic impairments were the most prevalent, accounting for 13.6 million impairments or 71.8% of the impairments due to injuries. The majority of these deformities were of the back and of the lower extremities or parts of the extremities. Hearing impairments were the second most prevalent, adding up to 1.5 million conditions or 8.1% of the total.

This report shows that there are sub-



Other selected impairments (7.1%)
Complete or partial paralysis of extremities (1.4%)
Visual impairments (4.8%)
Absence of or parts of extremities (6.8%)
Hearing impairments (8.1%)
Deformities or other orthopedic impairments (71.8%)

FIGURE 1—Percent of selected impairments due to injuries by type of impairment: United States, 1985 to 1987.

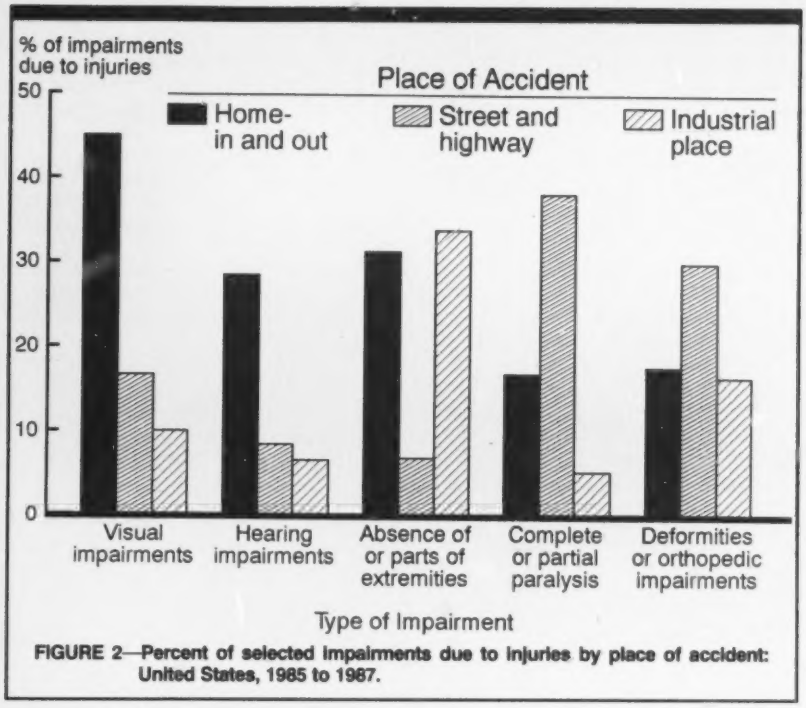


FIGURE 2—Percent of selected impairments due to injuries by place of accident: United States, 1985 to 1987.

stantial differences among various sociodemographic groups. One interesting finding was the difference between men and women. The prevalence rates for all types of selected impairments due to injuries, except for deformities and orthopedic impairments of the back, were higher among men than women.

A second interesting finding was the relationship between injuries and age. Adults aged 45 years and older had higher prevalence rates for all major categories of impairments due to injuries than younger adults. For example, there were 47 deformities or orthopedic impairments per 1000 adults under 45 years of age compared with over 80 per 1000 adults 45 years of age and older.

Another interesting finding was the relationship between injuries and family income. In general, the prevalence of injury-related impairments was inversely associated with income. For example, people in families with incomes of less than $10 000 had higher prevalence rates for visual impairments and deformities or orthopedic impairments than persons with family incomes above $10 000.

The report also provides data on the place where the injury that resulted in the impairment occurred, data that can be used for the targeting of prevention programs. More than one out of four impairments due to injuries occurred in accidents on streets or highways. The second most common place of accident resulting in an impairment was the home: more than one out of five impairments were due to injuries that occurred at home.

Targeting can even be more specific. Some impairments due to injuries were disproportionately represented among primary places of accident (Figure 2). For example, almost one half (45%) of visual impairments and nearly one third (31%) of impairments involving a loss of extremities or parts of extremities were caused by an injury at home. Almost two out of every five cases of paralysis of extremities or parts of extremities due to injuries occurred in accidents on the street or highway. The street or highway was also the most likely place of accident responsible for deformities or orthopedic impairments caused by injuries.

Selected Impairments Due to Injuries shows that the consequences of preventable disability are significant. Many of the impairments due to injuries resulted in a limitation of activity (defined as a long-term reduction in a person's capacity to perform the average kind of activities associated with his or her age group). Almost half (47%) of all physical impairments caused by injuries led to a limitation of activity. For some types of impairments this figure is even higher; for example, 87% of paralysis of extremities or parts of extremities resulted in a limitation of activity.

Injury-related impairments also led to substantial levels of restricted activity (defined as a short-term reduction in a person's activities below his or her normal capacity). 275 million days of restricted activity per year, or about 15 days of restricted activity per impairment, occurred as a result of preventable disabilities. Furthermore, approximately 88 million days per year confining people to their beds because of disability were due to injury-related impairments; this averages to 4.7 bed disability days per impairment.

Physical impairments caused by injuries not only lead to decreases in productive activity, temporary or permanent, but significantly affect overall health status as well. The results of this report point to a strong association between respondent-assessed health status and impairment due to injuries. For all of the major categories of physical impairments, the annual prevalence rates were markedly high among persons reporting a fair or poor health status. For example, the annual prevalence rate for deformities or orthopedic impairments due to injuries among persons reporting a fair or poor health status was almost twice that of persons reporting a good health status (137.6 compared with 71.9 impairments per 1000 persons per year). Thus, an injury-related impairment may, in fact, be a primary cause of differences in self-assessed health status.

Selected Impairments Due to Injuries contains data on the prevalence and associated consequences of preventable disabilities in the United States and also provides information vital to public efforts aimed at prolonging the active life of individuals. With better insight into the population groups most at risk of impairments due to injuries and with better knowledge of the primary places and types of accidents leading to impairments, public programs to reduce one of the major causes of disability in the United States can be more effectively designed and implemented. □

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 Fifteenth St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Mervyn Susser, DPH, Editor, *American Journal of Public Health,* 1015 Fifteenth St., NW, Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication and are not under consideration elsewhere.

Subscription price, individual, is $80/year US, $120/year international; **institutional,** $160/year US, $240/year international. Single copies $10 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 Fifteenth St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters.

Advertising Sales: Mary Beth Schultz, Advertising Manager, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal of APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact: Marilyn Butler, AJPH Reprints, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols. 1 to present are also available on microfilm.

Exposure to Environmental Tobacco Smoke in Naturalistic Settings

ABSTRACT

Background. Exposure to environmental tobacco smoke (ETS) has been identified as a risk factor for chronic disease among nonsmokers. Results of epidemiological surveys suggest that the majority of nonsmokers have regular ETS exposure. However, little is known about the topography of exposure.

Methods. An exposure diary was used by 186 nonsmokers to self-monitor ETS exposure over a 7-day period. Subjects also completed a questionnaire that assessed their patterns of ETS exposure.

Results. The primary source of ETS exposure was the workplace, except when there was a smoker in the household, in which case the household was the primary source. The presence of a smoker in the household resulted in higher levels of exposure both at work and in other locations when compared with subjects without household exposure. Subjects' assessments of exposure on the questionnaire were consistently lower than their self-monitored levels. This finding suggests that general exposure ratings underestimate exposure.

Conclusions. This study provides a new understanding of the patterns of ETS exposure and may help guide the development of policies and interventions designed to reduce ETS exposure. (*Am J Public Health.* 1992;82:24–28)

Introduction

Exposure to environmental tobacco smoke (ETS) has been identified as a risk factor for lung cancer and chronic obstructive pulmonary disease among nonsmokers.[1–7] Exposure to ETS increases acute respiratory symptoms and leads to a decrement in pulmonary function.[8–12] Results of population-based surveys suggest that 88% of nonsmokers are aware of the negative health consequences of passive exposure to tobacco smoke.[13] Despite this general awareness, however, exposure to ETS is pervasive. More than 55% of the respondents to the Adult Use of Tobacco Survey reported that their workplace did not have any smoking restrictions.[13] In an interview study, Cummings and colleagues found that over 75% of nonsmokers (n = 663) reported ETS exposure in the 4 days prior to their participation in the study.[14]

We must assess the pattern and degree of ETS exposure if we are to understand the disease risk associated with exposure and evaluate the success of interventions designed to minimize such exposure. The focus of this paper is on the measurement of acute daily exposure in field settings. One problem with measuring ETS exposure is that estimates of exposure are often based on global survey measures that rely on subjective estimates of quantity (e.g., "a little," "some," or "a lot"),[15] often over nonuniform periods of time. In addition, survey measures have been incomplete in assessing the parameters of exposure, such as location, source, intensity, duration, and ventilation.[16–18] Therefore, although some global measures have been useful, it is difficult to obtain specific estimates of the parameters of exposure on the basis of information obtained with survey measures.[18]

Little is known about the precise parameters of exposure among nonsmokers in the natural environment. Knowledge about these parameters of exposure is important for intervention, public health education, and policy efforts designed to reduce overall ETS exposure.[7,19] In this paper, by estimating daily exposure, we provide situation-specific information (place, time, intensity, and proximity) that may be useful for individuals in planning avoidance or reduction strategies to minimize their exposure to ETS and for policymakers to improve the protection of the public's health.[20]

The data presented here are from a larger study designed to develop interventions to reduce ETS exposure in the workplace. The purpose of the present study was to develop a method for self-monitoring ETS exposure continuously over a 7-day period, to use this method to document the frequency of exposure in natural

This paper was submitted to the journal August 9, 1990, and accepted with revisions May 6, 1991.

settings, and to document selected exposure parameters. Results obtained with this self-monitoring technique were also compared with global ratings typically used in survey research.

Methods

Subjects

Recruitment efforts were focused on nonsmokers in workplace settings that were selected to have a wide range of exposure to ambient ETS. The work sites ranged from those with minimal restriction of smoking and high levels of exposure (e.g., long-term care and psychiatric facilities, chemical dependency treatment centers, a VA Hospital) to work sites with extensive smoking restrictions and low exposure (e.g., the state health department and community hospitals). Approximately two thirds of the participants were recruited directly from workplaces, and the remainder were recruited via newspaper advertisements.

Of 224 nonsmokers who volunteered to participate in a study of passive smoking, 38 were excluded because of incomplete data. The demographic characteristics of the sample are presented in the Table. The subjects' mean age was 41.7 years (SD = 12.2). Their mean educational level was 15.8 years (SD = 2.8), and their income range (modal) was $30 000 to $49 999. Ninety percent of the subjects worked outside the home. Eighty-four percent of those who worked outside the home (75.6% of the total sample) reported being regularly exposed to smoking in the workplace. Thirty percent of the subjects reported living with one or more (range: one to four) smokers.

Measures

Exposure questionnaire. The exposure questionnaire provided a global estimate of subjects' exposure to ETS. The questionnaire was designed to elicit information about the respondents' perception of their level of ETS exposure (number of minutes per day, intensity of exposure) at various locations (work, home, and other). Several knowledge and attitude questions from the Office on Smoking and Health's 1988 Adult Use of Tobacco Survey[13] were included; results based on these items will be presented elsewhere.

Exposure diary. The exposure diary consisted of small (3.5 × 5 inches) printed cards (see Figure 1). Each entry required only a simple check mark or short response, which subjects were asked to make at the time of exposure. Subjects were instructed to define "exposure" as contact with an individual who was actively smoking. The parameters assessed by the diary included number and duration of exposures location of exposure (work, home, other), intensity of exposure (number of smokers), and distance from the source of exposure ("near" = less than 5 feet; "far" = more than 5 feet).

Procedure

A research assistant met with all subjects on two separate occasions (1 week apart) to administer the exposure questionnaire, to train subjects in the use of the exposure diary, and to collect the data. To facilitate appropriate use of the exposure categories, the research assistant had the subjects code several sample exposure scenarios and provided feedback about their coding accuracy. Self-monitoring began on the day after the training session and continued for 7 consecutive days. The distribution of the initial day of monitoring across the days of the work week was approximately equal.

Ideally, the global exposure questionnaire and the exposure diary would have been collected over the same time interval. However, the act of self-monitoring (keeping the diary) would presumably have enhanced the accuracy of the global responses and confounded any meaningful comparison of the two approaches. To minimize this confound, the exposure questionnaire was administered first, asking about the preceding 7-day period. After they completed the questionnaire, the subjects were trained in the use of the 7-day exposure diary. To make the two 7-day time periods as comparable as possible, the subjects were asked to participate in the study during a 2-week time period that reflected their typical daily lifestyle (e.g., at a time when they were not on vacation).

Results

Data Stability

Exposure duration was similar when examined across different segments of the monitoring period (7 days vs last 3, 2, and 1 days); there were no significant differences among the four sampling intervals, and the Pearson product-moment correlations among the intervals ranged from .85 to .97. Therefore, average daily exposure based on information in the 7-day diary was used for all analyses.

TABLE 1—Description of Study Sample (n = 186)

	n	%
Sex		
Male	69	37
Female	117	63
Marital status		
Single/divorced	58	31
Married/cohabiting	128	69
Ethnic group		
White	181	97
Black	5	3
Smoking status		
Never a smoker	115	62
Ex-smoker	71	38

Data Reduction

Individual exposure durations were calculated from the start and stop times of each exposure noted in the diary. Total duration of exposure (in minutes per day) was derived from the sum of the individual episodes of exposure. Exposure duration was computed for the entire 7-day monitoring period. To assess the potential influence of reactivity and response burden, the relative stability of shorter sampling intervals (24, 48, and 72 hours vs 7 days) was also computed.

Parameters of Exposure Determined by the Exposure Diary

Duration of exposure by location. In the total sample, as indicated in Figure 2, significantly more of the exposure was encountered at work, with home and "other" contributing less to overall exposure. Approximately 50% of the exposure was in the workplace; the home environment accounted for 10% of the total daily exposure. However, when those with and those without a smoker in the household were examined separately, we found that subjects who lived with a smoker received more exposure in the home than in the workplace, omnibus $F(33) = 4.47$, $P \leq .01$ (see Figure 3).

The presence of smokers in the home had a significant effect on duration of exposure across specific settings. Subjects without smokers at home reported that the majority of their exposure was in the workplace (mean = 36.1 minutes per day, 95% confidence interval [CI] = 22.7–49.5), with very little either at home (mean = 1.4 minutes per day, 95% CI = 0.05–2.75) or in other locations (mean = 13.1 minutes per day, 95% CI = 8.75–17.4). However, subjects who lived with smokers had virtually equivalent exposure across all three settings (work: mean = 29.4 minutes per day,

FIGURE 1—Exposure diary.

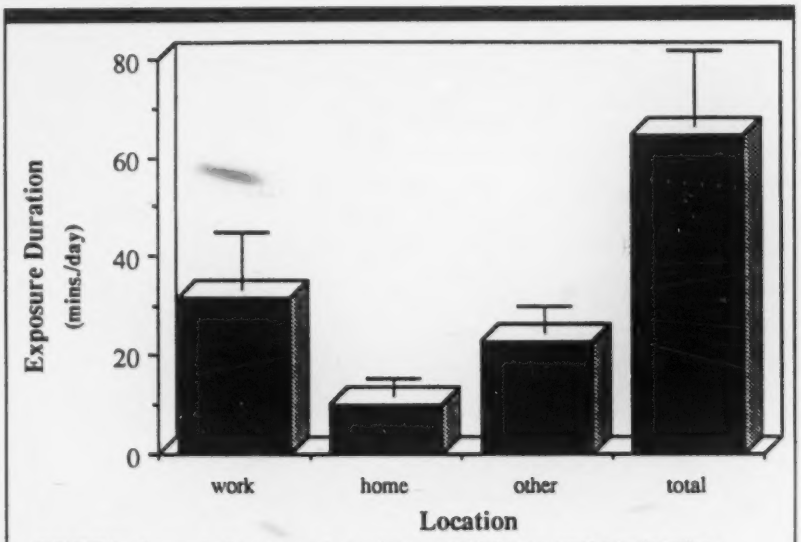

FIGURE 2—Amount of exposure to environmental tobacco smoke by location.

95% CI = 7.01–51.80; home: mean = 31.2 minutes per day, 95% CI = 21.6–40.8; other: mean = 27.1 minutes per day, 95% CI = 15.1–39.1).

To further examine differences between subjects with differing levels of exposure, we used a tertile split based on the average daily exposure to divide the sample into three levels of exposure: low (0–7 minutes per day), moderate (8–44 minutes per day), and high (≥45 minutes per day). These categories are somewhat arbitrary, because no standard has been set in the field about the severity of various gradients of exposure. Subjects in the high-exposure category were more likely to have smokers both at home, $F(2) = 4.93$, $P \leq .01$, and at work, $F(2) = 3.11$, $P \leq .05$. They also had more friends outside the workplace who were smokers, $F(2) = 5.31$, $P \leq .01$.

Intensity of exposure. Ratings of distance from the source of exposure were used as a measure of exposure intensity. We compared the percentages of exposure at each location (home, work, other) that occurred near and far from the subject (see Figure 4). Significantly more of the exposure occurring at home was close to the subject, and therefore more intense, compared with exposure at work and other locations.

Relationship between the Exposure Diary and Exposure Questionnaire

Subjects were asked on the exposure questionnaire to provide a global rating of their ETS exposure on a three-point scale (low, moderate, high). Fifty-three percent of the sample rated their exposure as low. Thirty-six percent rated their exposure as moderate, and 11% as high. Subjects who rated their overall exposure as low had an average of 18.59 minutes of exposure per day (SD = 27.08, range = 0.0–203.0), compared with an average of 110.28 minutes per day (SD = 142.82, range = 0.0–603) for subjects who rated their exposure as moderate and an average of 132.24 minutes per day (SD = 115.15, range = 8.67–408.0) for those who rated their exposure as high.

Correlational analyses were used to compare the exposure diary data with global estimates from the exposure questionnaire across locations (home, work, other). The correlation was strongest between global and diary estimates of exposure at home, $r(185) = .62$, $P \leq .001$ (95% CI = .58–.87), but all correlations (work, $r = .40$; other, $r = .29$; overall, $r = .44$) were significant at $P \leq .01$.

Relationships between Demographics and Exposure

Exposure was significantly related to education, $r(185) = -.22$, $P \leq .01$ (95% CI = −.37 to −.08): exposure was higher among less educated subjects. The relationship between gender and exposure was marginally significant ($P = .10$), indicating a trend for men to have higher levels of exposure than women. No other relationships between demographics and exposure were significant.

Discussion

This study represents one of the first attempts to develop a prospective, diary measure of daily exposure to ETS, to examine sources of exposure for a 1-week period, and to compare the diary with a global questionnaire measure of exposure. We found the exposure diary to be a relatively simple and effective method of assessing ETS. Furthermore, the data were quite stable, as evidenced by the high correlation between the 1-, 2-, 3-, and 7-day blocks of self-monitored exposure. Thus, a 1- or 3-day diary may be preferred to reduce response burden.

The majority of ETS exposure occurred in the workplace. The percentage of subjects reporting exposure at work (75.6%) replicates that found by Cummings et al.[14] (75%) in a different sample. Furthermore, both the duration and the intensity of exposure were greater for subjects with a smoker in the household,

regardless of the degree of exposure in the workplace. Importantly, subjects with smokers in the home had virtually equivalent exposure across all settings, whereas subjects who did not live with smokers had the majority of their exposure at work and very little in other settings. This suggests that nonsmokers who live with smokers are exposed outside the home to a greater degree than nonsmokers who have no smokers in the household. The reasons for this are unclear, but it is possible that these nonsmokers have less motivation to avoid ETS exposure in general, because they cannot avoid it at home. As expected, subjects in the highest exposure category had regular ETS exposure both at work and at home. These data suggest that for intervention efforts to be effective for those subjects at highest risk, they need to be focused on all sources of exposure—particularly if there is a smoker in the household.

The subjects' own assessments of their exposure levels on the questionnaire were consistently lower than the levels determined by the diary, suggesting that studies utilizing global exposure ratings from surveys may underestimate actual exposure. This may be due in part to the insidious nature of exposure—a high level of vigilance is necessary if accurate estimates are to be obtained. In this case, self-monitoring techniques may increase the accuracy of exposure estimates. Survey-based estimates may also be lower because of the unpredictability of ETS exposure. As noted earlier, the exposure diary and the exposure questionnaire relate to different time periods, 1 week apart. This was necessary to minimize the confound that might have resulted from the increased awareness of exposure due to self-monitoring, which might have influenced responses to the exposure questionnaire. Since both time periods were regarded as typical, and since there was high stability between the 1-, 2-, 3-, and 7-day average exposure durations, it is unlikely that the different sampling intervals alone accounted for the underestimates of the exposure questionnaire.

The subjects in this study were volunteers who responded to advertisements for a study on passive smoking, and thus were a motivated sample of convenience. A selection bias or social desirability bias may have been operating, so that participants may have been more vigilant about noting their exposures to ETS than persons in a random sample might have been. However, the recruitment protocol was designed to target individuals with a wide range of ETS exposure in order to increase the representativeness of the sample. The amount of exposure across individuals in the sample varied considerably, suggesting that the population was not homogeneous. In addition, the demographics of this sample were virtually identical to those found in population-based samples by, for example, Marshall et al.[21] Thus, it does not appear that a significant selection bias was operating.

One concern about the use of the diary is the recall bias that may be introduced if exposures are not recorded at the time they occur. Although some diary entries may have been made after the actual exposure, every effort was made to minimize such occurrences (training emphasized immediate completion, and the diary was designed to minimize response burden). In addition, the subjects were asked during debriefing about the case of diary completion, and few reported having difficulty completing the diary as instructed.

This study provides further understanding of the patterns of ETS exposure in natural settings. It also sheds light on the relationship between retrospective global estimates of exposure and prospective recording of actual exposure as it oc-

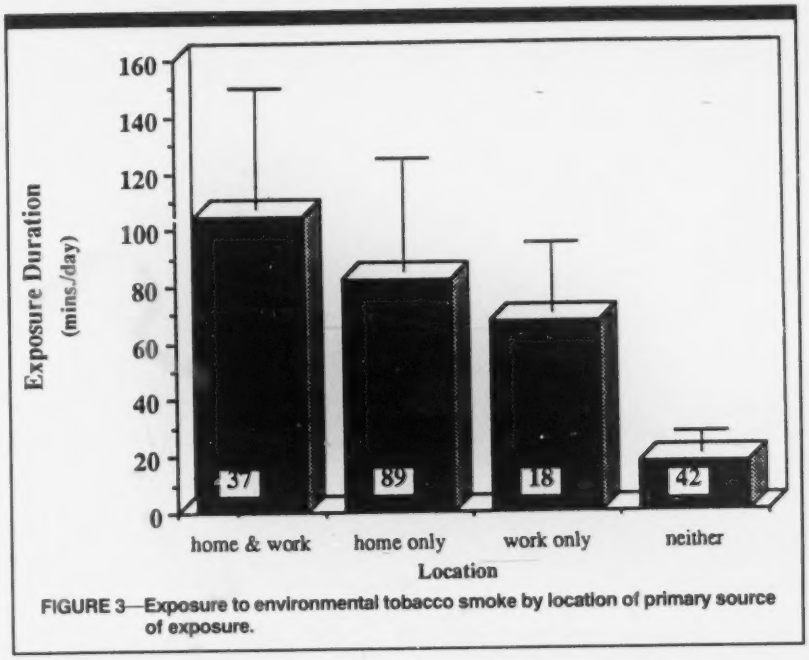

FIGURE 3—Exposure to environmental tobacco smoke by location of primary source of exposure.

curs in the field. This comparison is tempered by the methodological limitations that precluded assessment of both measures in the same time period. These data may be useful in developing effective public health policies and in designing intervention programs targeted at both individuals and organizational settings to reduce nonsmokers' exposure to ETS. □

Occupational Risks Associated with Cigarette Smoking: A Prospective Study

James Ryan, MD, MPH, Craig Zwerling, MD, PhD, MPH, and Endel John Orav, PhD

ABSTRACT

Background. Studies have indicated that cigarette smokers have more occupational accidents and injuries and use more sick time and health benefits than nonsmokers, thereby producing sizeable costs for employers. However, they usually have not controlled for other possible sources of these costs. We analyzed occupational costs associated with smoking while adjusting for a number of potential confounders.

Methods. We conducted a prospective, controlled study of the association between smoking and employment outcomes in 2537 postal employees, adjusting for age, gender, race, drug use, job category, and exercise habits.

Results. For smokers, the relative risk for turnover was 1.01 (95% confidence interval [CI], 0.83–1.21); for accidents 1.29 (CI, 1.07–1.55); for injuries 1.40 (CI, 1.11–1.77); for discipline 1.55 (CI, 1.19–2.02). Their mean absence rate was 5.43% compared with 4.06% for nonsmokers.

Conclusions. Our study shows that cigarette smoking is associated with adverse employment outcomes after controlling for a number of possible confounders. This finding has implications for companies formulating smoking policies and considering the establishment of smoking cessation programs. (*Am J Public Health.* 1992;82:29–32)

Introduction

The social costs of cigarette smoking, including occupational risks, have been widely discussed since the original surgeon general's report on smoking and health.[1,2] A 1986 study of public employees found that cigarette smokers use 23% more sick leave than nonsmokers.[3] Studies of student nurses in 1983 and 1988 found smokers absent 77% more frequently than nonsmokers[4] and a significant relationship ($P < .008$) between number of cigarettes smoked and days absent.[5] Smokers have been reported to use more health benefits[6,7] and have more occupational accidents and injuries. A 1966 study of machinists reported an injury rate of 18% for smokers compared with 10% for nonsmokers; 26% of injured smokers reported multiple injuries vs 13% of injured nonsmokers.[8] A 1973 study involving ceramics workers[9] found that 57% of smokers sustained occupational injuries and 20% lost time from work as a result of injury. Among nonsmokers, only 28% sustained injuries and 10% lost time. These associations account for sizable costs for employers of smokers.[10,11]

Smoking rates vary with demographic variables, including age, sex, and race.[2] Smoking is also associated with use of drugs[12] and excessive alcohol.[13,14] Since such factors may be associated with adverse health outcomes, studies of risks associated with smoking should control for these potential confounding variables.

We present a prospective examination of the association between cigarette smoking and rates of employee turnover, absenteeism, accidents, injuries, and discipline while controlling for age, gender, race, job category, exercise habits, and drug abuse. It represents a secondary analysis of data collected in a previous study of the predictive value of preemployment drug testing.[15]

Methods

Cohort Definition

All Boston postal service applicants for permanent nonprofessional positions examined between September 24, 1986, and January 6, 1989, were potential study subjects. Candidates for temporary and professional positions were excluded, the latter because of their small number (n = 11) and different socioeconomic and educational backgrounds.

From September 24, 1986, to January 6, 1989, 4957 applicants received preemployment examinations. We excluded 56 applicants because data-entry errors made it impossible to track their outcome variables, 60 Hispanics (of whom 24 were hired) and 2 Native Americans (1 hired) because the numbers were too small for statistical analysis, and 42 applicants with a history of treatment for drug abuse and

7 who tested positive for opiates under a prior agreement with postal service management to fully evaluate such persons. Thus, the study population was not entirely representative of all postal service employees hired during the study period. Persons removed from the study were excluded without consideration of their smoking status. Of the remaining 4797 applicants, 2 for whom data on smoking status were unavailable were excluded, leaving 4795 potential subjects for this study; 2537 applicants hired before January 28, 1989, were included. Both mean and median duration of follow-up were 406 days, with a range of 28 to 896 days.

Smoking Status

Smoking status was categorized as smoker or nonsmoker using self-reported data. Persons who had smoked three or more cigarettes per day over the previous month were classified as smokers. All other subjects were classified as nonsmokers. One tenth of 1% of subjects were smokers who smoked less than three cigarettes per day. Any misclassification bias introduced by this classification system would therefore be negligible and, in any case, toward the null.

Self-reported information on smoking status was used because of its convenience, simplicity, economy, and reliability. Self-reported data have been demonstrated to have sensitivity and specificity in excess of 90% when compared with objective measurements of saliva cotinine,[16] serum thiocyanate,[17] and expired carbon monoxide.[17,18]

Confounding Factors

A number of confounding factors might be associated with both the risk variable (cigarette smoking) and the outcome variables (turnover, absenteeism, accidents, injuries, and discipline). We therefore collected data on age, gender, race, job classification, drug use, and exercise habits.

Race was classified by the examiner as White, Black, or Asian. Job classifications included letter carrier, special delivery messenger, motor vehicle operator, postal clerk, letter sorting machine clerk, computer forwarding system clerk, mail handler, and maintenance worker, divided into two or three categories according to endpoint. Applicants were divided into "aerobic exercisers" (strenuous exercise for 20 minutes, three times a week), "regular exercisers," and "nonexercisers" based on self-report. A urine drug screen was performed for marijuana, cocaine, amphetamines, barbiturates, benzodiazepines, methadone, methaqualone, opiates, phencyclidine, and propoxyphene as reported elsewhere.[15] In the analysis, drug test results were classified into four categories: negative for all drugs, positive for marijuana only, positive for cocaine only, and positive for other drugs or multiple drugs.

Endpoints

Five endpoints were considered in the analysis: absence rate, time to termination, time to first accident, time to first injury, and time to first discipline.

Absence rates. The absence variable was a function of sick leave (SL), leave without pay (LWOP), and work hours calculated according to the following formula:

$$\text{Absence rate} = \frac{\text{SL hours} + \text{LWOP hours}}{\text{SL hours} + \text{LWOP hours} + \text{work hours}}$$

Time to termination. Individuals whose employment with the postal service had terminated were defined as having turned over. Termination was subdivided into two categories, voluntary (death, resignation, or transfer to another federal agency) and involuntary (fired).

Time to first accident. Records of work-related accidents revealed a relatively low rate of multiple accidents. Of 502 employees reporting accidents, 76 had two accidents and 14 had three. We therefore analyzed time to first accident rather than accident rates.

Time to first injury. We found a relatively low rate of multiple injuries. Of 312 employees who reported occupational injuries, 41 had two injuries and 8 had three. We therefore analyzed time to first injury rather than injury rates.

Time to first report of disciplinary action. The postal service labor agreements provide for progressive levels of discipline up to removal. The time to first discipline was calculated from labor relations department records. All endpoints were followed through March 11, 1989.

Statistics

We used the Cox proportional hazards model[19] from the SAS statistical package's SUGI supplement[20] with nonsmokers as the baseline group to assess whether cigarette smoking was associated with turnover, accidents, injuries, or discipline. Thus, a significantly positive Cox regression coefficient for smokers indicates a significantly increased risk for that endpoint and a negative Cox regression coefficient indicates a decreased risk.

Because 25% of the subjects had a 0% absence rate, it was not possible to use linear regression with absence rate as the outcome variable. Subjects who were absent were divided into approximately equal quartiles according to their absence rates: 0% absence rate (n = 646), 0% to 1.52% (n = 478), 1.52% to 3.04% (n = 468), 3.04% to 5.60% (n = 471), and absence rate > 5.60% (n = 474). The SAS polychotomous logistic regression was used to determine whether smoking was associated with an increased risk of being in a high-absence category.

The potential confounding variables (age, sex, race, drug use, job classification, and exercise) were simultaneously entered into the Cox and logistic regression models, permitting adjustment for confounding with cigarette smoking.[21] All *P* values were two sided and considered significant at a .05 level.

Results

Of the 4795 eligible applicants, 2537 were hired. There was no difference in smoking rate between those hired (32.5%) and not hired (33.2%; $P = .62$).

Table 1 presents the distribution of covariates. Smokers were more frequently older, female, nonexercisers, and drug users and less often Asian or letter carriers. Thus, these variables were potential confounders.

Table 2 shows measures related to the endpoints correlated with smoking status. Since the distribution for absence rate was skewed markedly to the right, both mean and median are provided. While this table does not include adjustments for covariates, inclusion of covariates in the Cox proportional hazards and polychotomous logistic regression models resulted in only small changes. Thus, these covariates were not major confounders in our data set.

Table 3 presents the results of the Cox proportional hazards models with inclusion of covariates. Cigarette smokers show increased risks of accidents, injuries, and discipline but no increased risk of termination.

A polychotomous logistic regression model was used to predict absence category with the covariates included. This analysis produced a beta for smokers of 0.264 with a *P* value of .0007. Interpretation of an odds ratio for absence is not

intuitive, as absence is divided into five leave-use categories. Mean absence rates provide a more easily interpreted estimate of the magnitude of the effect: 5.43% for smokers and 4.06% for nonsmokers.

Discussion

To our knowledge, this study presents the first prospective estimates of associations between cigarette smoking and adverse employment outcomes after adjustment for the potentially confounding covariates of age, sex, race, exercise, drug abuse, and job category. We found significant positive associations between cigarette smoking and absenteeism, industrial accidents, occupational injuries, and disciplinary action. Smokers had a 34% increase in mean absenteeism that remained significant after adjustment for covariates. Smokers had increased covariate-adjusted relative risks for industrial accidents (29%), occupational injuries (40%), and discipline (55%). We found no significant difference in turnover, voluntary or involuntary. Thus, our study confirms the previously reported elevated rates of absenteeism, accidents, and injuries for smokers.[3-9]

The mean age of our study population was 30.2 years. In our cohort of newly hired younger workers, any increase in absence from smoking-related illness is most likely due to acute, short-term illnesses such as respiratory infections. The more serious adverse health outcomes caused by cigarette smoking, cardiovascular and chronic pulmonary disease and cancers, probably would not develop until workers are several decades older. The increase in smoking-associated absenteeism in our cohort, therefore, probably underestimates the true magnitude of this effect for workers who smoke throughout their working lives. A similar analysis might be made for use of health insurance benefits, a factor that we did not assess but that has been reported to be increased in smokers.[6,7]

In this study, we were unable to control for the possible confounding effect of alcoholism. Smoking is reported to be associated with alcoholism.[13,14] Alcoholics are also known to have poor employment outcomes.[22] We did not conduct any laboratory tests for alcohol abuse, as the methodologies available lack adequate sensitivity and specificity. We also did not use self-reports, as surveys of alcohol use have consistently demonstrated underreporting, even in settings where there would be no adverse consequences for positive reports.[23] The validity of self-reported data would be highly questionable in the preemployment examination setting.

Since we did not control for the effects of alcohol abuse, it is possible that some of the associations demonstrated are attributable to alcoholism rather than smoking. The degree of any confounding by alcoholism would be a function of the coincidence of alcohol and tobacco abuse in our study population. It might, therefore, affect the degree to which the results of this research can be generalized to populations with different alcohol- and tobacco-abuse patterns.

Our study cannot distinguish adverse employment outcomes associated with cigarette smoking caused by the physiological effects of smoking from those caused by smoking behavior (e.g., decreased attention to driving) or by other social or personality characteristics associated with smoking. The postal service smoking policy in effect during the first 28 months of the study permitted either un-

TABLE 1—Demographic Characteristics of the Study Population

Mean absence rate (%)	4.1	5.4
Median absence rate (%)	1.8	2.3

Note. Reported percentages represent the simple overall proportion of employees for whom the endpoint occurred; time- and covariate-adjusted analyses are reported in Table 3.

TABLE 3—Covariate-Adjusted Risks for Smokers Relative to Nonsmokers

	Relative Risk	*P* Value	95% Confidence Interval
Turnover	1.01	.956	0.83, 1.21
Voluntary	0.94	.585	0.74, 1.19
Involuntary	1.17	.306	0.86, 1.60
Accidents	1.29	.008	1.07, 1.55
Injuries	1.40	.004	1.11, 1.77
Discipline	1.55	.001	1.19, 2.02

Note. The risk estimates have been adjusted for age, gender, race, drug use, exercise habits, and job classification.

limited smoking at work or regular smoking breaks. For the last 3 months of follow-up, smoking was permitted during breaks every 2 hours. Thus, the effects of nicotine withdrawal would not have contributed to accidents or injuries. Although we cannot determine the etiology of the adverse employment outcomes, our findings provide a basis for estimating the magnitude of the increase in costs to industry that results from hiring cigarette smokers.

The findings of this study may also be useful in assessing the cost-effectiveness of corporate smoking control and smoking cessation programs. To the degree that such programs decrease cigarette smoking in the work force, a health-related effect such as absenteeism might be expected to decrease. It is less clear whether there would be similar improvements in effects such as accidents, injuries, and discipline, as these may be linked to social and behavioral characteristics that might persist after cessation of, or a decrease in, smoking. A comparison of smokers, former smokers, and persons who have never smoked might begin to answer such questions. We hope, however, that the present study will contribute to the body of knowledge needed to evaluate some of the complex ethical, legal, economic, and social issues related to smoking in the workplace. □

Misclassification of Smoking Status in the CARDIA Study: A Comparison of Self-report with Serum Cotinine Levels

Lynne E. Wagenknecht, DrPh, Gregory L. Burke, MD, Laura L. Perkins, PhD, Nancy J. Haley, PhD, and Gary D. Friedman, MD

ABSTRACT

Background. Although widely used in epidemiological studies, self-report has been shown to underestimate the prevalence of cigarette smoking in some populations.

Methods. In the CARDIA study, self-report of cigarette smoking was validated against a biochemical marker of nicotine uptake, serum cotinine.

Results. The prevalence of smoking was slightly lower when defined by self-report (30.9%) than when defined by cotinine levels equal to or greater than 14 ng/mL (32.2%, $P < .05$). The misclassification rate (proportion of reported nonsmokers with cotinine levels of at least 14 ng/mL) was 4.2% and was significantly higher among subjects who were Black, had a high school education or less, or were reported former smokers. Possible reasons for misclassification include reporting error, environmental tobacco smoke, and an inappropriate cutoff point for delineation of smoking status.

Using self-report as the gold standard, the cotinine cutoff points that maximized sensitivity and specificity were 14, 9, and 15 ng/mL for all, White, and Black subjects, respectively. The misclassification rate remained significantly higher in Black than in White subjects using these race-specific criteria.

Conclusions. Misclassification of cigarette smoking by self-report was low in these young adults; however, within certain race/education groups, self-report may underestimate smoking prevalence by up to 4%. (*Am J Public Health.* 1992;82: 33–36)

Introduction

Self-report is widely used to estimate the prevalence of cigarette smoking although it has been reported to underestimate the true prevalence in some populations.[1] Consequently, a number of biologic markers have been used to validate smoking, particularly in studies of cessation and of adolescent smoking.[2] Few studies have examined the validity of self-report in a general population sample of smokers and nonsmokers, nor in a sample of Blacks.

The purpose of this study is (1) to measure the discrepancy between smoking prevalence rates as defined by self-report and by serum cotinine, an objective measure of nicotine exposure, using a cotinine cutoff point of 14 ng/mL;[3,4] (2) to assess the degree of misclassification of reported nonsmokers by race, education, and past smoking behavior; and (3) to investigate possible reasons for misclassification.

Methods

The CARDIA study, a longitudinal epidemiological study of the risk factors for cardiovascular disease in a cohort of 5115 young adults aged 18 to 30 years, has been described previously.[5–7] The cohort was recruited to consist of approximately equal numbers of Black and White men and women of varied educational backgrounds. The data for this report were collected at the first clinical examination conducted in 1985 and 1986.

Smoking habit was assessed during the examination by interview. Smokers were defined as subjects who reported current, regular use of cigarettes (at least five cigarettes per week, almost every week). Nonsmokers were classified further as former smokers or as people who never smoked. Subjects who were reported being nonsmokers of cigarettes but who reported the current use of either cigars, pipe tobacco, smokeless tobacco, or nicotine gum were excluded from the analyses.

Smoking habit was also assessed at the recruitment telephone contact approximately 1 month prior to the examination. A smoker was defined as someone who smoked at least 100 cigarettes in his or her lifetime and who currently smoked. The reported number of hours per week that subjects were exposed to cigarette, cigar, or pipe smoke from others in their home was used as a measure of environmental tobacco smoke (ETS) exposure.

Serum cotinine was measured by radioimmunoassay[8,9] at the American Health Foundation in Valhalla, NY. Standard quality control procedures were followed; the interassay coefficient of variation was 7%. Based on previous investigations,[3,4] cotinine levels equal to or greater than 14 ng/mL were considered

TABLE 1—Comparison of Smoking Prevalence Defined by Cotinine Versus Self-report, by Race and Education

Race/Education	n	Smoking Prevalence (%) Defined by Cotinine ≥ 14 ng/mL	Defined by Self-report	Difference	(95% CI)
Black ≤ HS	1317	47.1	43.8	3.3	(2.0,4.6)
Black > HS	1255	25.7	23.9	1.8	(0.8,2.9)
White ≤ HS	660	48.5	47.7	0.8	(–1.0,2.5)
White > HS	1752	19.6	19.8	–0.2	(–0.7,1.1)
Overall	4984[a]	32.2	30.9	1.3	(0.8,1.9)

Note. CI = confidence interval. ≤ HS = a high school education or less; > HS = more than a high school education.
[a]Thirty-five subjects were missing responses about cigarette smoking, 46 did not have cotinine results, and 48 reported use of other tobacco products, leaving 4984/5115 (97%) subjects available for analysis.

TABLE 2—Misclassification Rates, by Race and Education

Race/Education	All Reported Nonsmokers	Reported Never Smokers[c]	Reported Former Smokers
Black ≤ HS	8.2 (61/740)	5.1 (32/627)	25.7 (29/113)
Black > HS	3.7[aa] (35/955)	2.6[a] (22/841)	11.4[a] (13/114)
All Black	5.7 (96/1695)	3.7 (54/1468)	18.5 (42/227)
White ≤ HS	5.8 (20/345)	3.0 (7/230)	11.3[b] (13/115)
White > HS	2.1[aa,b] (29/1405)	1.0[a,b] (11/1092)	5.8[b] (18/313)
All White	2.8[bb] (49/1750)	1.4[bb] (18/1322)	7.2[bb] (31/428)
Overall	4.2 (145/3445)	2.6 (72/2790)	11.2 (73/655)

Note. Misclassification rate = proportion of reported nonsmokers with serum cotinine of at least 14 ng/mL. ≤ HS = a high school education or less; > HS = more than a high school education.
[a]$P < .05$, [aa]$P < .0001$ for difference in misclassification rates by education, within race.
[b]$P < .05$, [bb]$P < .0001$ for difference in misclassification rates by race, within education.
[c]All comparisons of misclassification rates by previous smoking history are significant, $P < .0001$.

TABLE 3—Distribution of Serum Cotinine Levels among Reported Nonsmokers and Smokers

Cotinine (ng/mL)	Reported Nonsmokers (n = 3445) n	Reported Nonsmokers (n = 3445) %[a]	Reported Smokers (n = 1539) n	Reported Smokers (n = 1539) %[a]
0–13	3300	—	78	—
14–49	72	49.7	133	9.1
50–99	23	15.9	142	9.7
100–149	15	10.3	206	14.1

[a]As a percent of all values of at least 14 ng/mL.

indicative of active smoking and not a result of ETS exposure.[10,11]

The Kolmogorov-Smirnov statistic was used to test for differences in the distributions of cotinine between Whites and Blacks and between former smokers and those who never smoked. Differences in ETS exposure between classes of nonsmokers were assessed using the Wilcoxon rank sum test. Confidence intervals were computed for differences between smoking prevalence rates using variance formulas for rate differences and taking the matched pairs into account.[12]

Results

Overall, the smoking prevalence rate as defined by cotinine levels of at least 14 ng/mL was 1.3 percentage points higher than that based on self-report (Table 1). The largest discrepancies were observed among the Black subjects; self-report underestimated smoking prevalence by 3.3 percentage points among Blacks with a high school education or less.

Of the 3445 reported nonsmokers, 145 had cotinine levels of at least 14 ng/mL, for a misclassification rate of 4.2% (Table 2). (The proportion of reported smokers with cotinine levels of less than 14 ng/mL was 78/1539, or 5.1%.) The misclassification rate was two times greater among Black subjects than among White subjects (5.7% vs 2.8%), almost three times greater among those with a high school education or less than among those with more than a high school education (7.5% vs 2.8%), and four times higher among the reported former smokers than among those who reported never having smoked (11.2% vs 2.6%, all $P < .0001$). Gender differences (not shown) were negligible.

The distribution of cotinine levels among the 145 subjects misclassified as nonsmokers differed from that among the true smokers, i.e., reported smokers with cotinine levels of at least 14 ng/mL (Table 3). One half of the misclassified subjects had cotinine levels between 14 and 49 ng/mL whereas less than 10% of the true smokers had cotinine levels in this range. The distribution of cotinine levels equal to or greater than 14 ng/mL was not significantly different either between former smokers and those who never smoked or between the races (not shown).

One half (73/144) of the subjects misclassified as nonsmokers reported spending most of their time around smokers whereas only 28% (906/3296) of the true nonsmokers (reported nonsmokers with cotinine of less than 14 ng/mL) reported this behavior ($P < .0001$). This was confirmed by their self-report of the number of hours they were exposed to ETS. The misclassified nonsmokers reported greater weekly exposure to ETS than the true nonsmokers (medians: 5 hours vs 0 hours, $P < .0001$); among the misclassified subjects, Blacks reported greater weekly exposure to ETS than Whites (medians: 6 hours vs 2 hours, $P = .02$). In addition, nearly one half (29/67) of the misclassified former smokers reported having quit smoking within the past year whereas only 20% of the true reported former

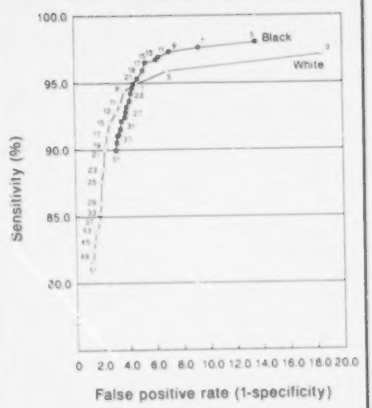

FIGURE 1—Receiver operating characteristic curve for varying levels of serum cotinine by race. The false positive rate (i.e., the proportion of reported nonsmokers whose cotinine level is equal to or greater than the given cutoff point) is the same as the misclassification rate as defined in this article. Levels of cotinine equal to or above the cutoff point are considered characteristic of a smoker. Self-report was considered truth for the calculation of these values.

TABLE 4—Sensitivity (%) and False Positive Rate (1-Specificity) for Various Cotinine Cutoff Values (ng/mL)

Cotinine Cutoff	Overall			Black			White		
	Sens.	False Pos. (1-Spec.)	Sum[a]	Sens.	False Pos. (1-Spec.)	Sum[a]	Sens.	False Pos. (1-Spec.)	Sum[a]
5	97.1	10.2	186.9	98.0	13.6	184.4	95.9	6.9	189.0

19	93.2	3.5	189.7	95.3	4.7	190.6	90.3	2.3	188.0

Note. Cotinine levels < cutoff indicate nonsmoker, levels ≥ cutoff indicate smoker. Number of reported nonsmokers: 1695 Blacks, 1750 Whites; number of reported smokers: 877 Blacks, 662 Whites.
[a]Sum = sensitivity + specificity.
[b]Point at which sensitivity and specificity are maximized. Note that only odd values of cotinine are presented except for the value of 14 ng/mL.

smokers reported having quit over that period ($P < .0001$). Note that denominators are reduced slightly due to missing values.

Approximately one third (42/145) of the subjects misclassified as nonsmokers had identified themselves as current smokers at the recruitment interview one month earlier. Misclassification rates, calculated using smoking status as obtained at recruitment, were slightly higher than and yet consistent with those presented in Table 1; rates were twice as high in Black subjects than in White subjects (8.8% vs 3.8%) and three times higher in the reported former smokers than in those who reported having never smoked (14.5% vs 4.5%).

To investigate the possibility that the misclassification of these 145 reported nonsmokers was due to the use of an inappropriate cotinine cutoff point, we examined the receiver operating characteristic curve, which plots sensitivity against the false positive rate[13] (Figure 1). Cutoff points in the upper left corner of the graph maximize sensitivity and specificity. For these analyses, self-report was considered truth.

The cotinine cutoff point that led to the best combined levels of sensitivity and specificity in the overall cohort was 14 ng/mL (Table 4; note that sensitivity and specificity are both quite high over a range of cotinine cutoff points, from 9 ng/mL to 16 ng/mL). The race-specific cutoff point that maximized these parameters in the Black subjects was slightly higher than that in the White subjects (Figure 1, Table 4). (This was true across the entire range of sensitivity and specificity.) Among Black subjects, a cutoff point of 15 ng/mL maximized these parameters, yielding a sensitivity of 96.5% and a specificity of 94.7% (false positive rate of 5.3%). (Note that the definition of the false positive rate is the same as that of the misclassification rate). Among White subjects, a cutoff point of 9 ng/mL maximized these parameters, yielding a sensitivity of 94.4% and a specificity of 96.3% (false positive rate of 3.7%).

Applying these race-specific cutoff points to the entire cohort, the overall misclassification rate for reported nonsmokers was 4.5% (155/3445); these rates remained higher in Black subjects, as shown above (5.3% vs 3.7%, $P < .05$). Using these race-specific cutoff points to define smoking prevalence led to findings similar to those reported in Table 1, with a significant yet smaller underestimation of prevalence among Blacks (and also a significant underestimation among Whites with a high school education or less).

Discussion

These data indicate that self-report is a fairly accurate estimator of smoking prevalence in young adults. However, judging by cotinine levels and using a cutoff point of 14 ng/mL, smoking prevalence is underestimated to a greater degree among Blacks than among Whites, among former smokers than among those who never smoked, and among those with a high school education or less than among those with more.

Four possible reasons for misclassification were considered: (1) data collection/entry errors, (2) reporting errors, (3) ETS exposure, and (4) use of an inappropriate cutoff point for delineation of smoking status. In response to the first possibility, data collection followed standard quality control procedures. No data entry errors were found.

As for the second possibility, several types of reporting errors could have occurred. First, the subjects may have misunderstood the smoking questions. In fact, 29% of the 145 misclassified subjects identified themselves as smokers at recruitment. (It is possible that some of these subjects quit smoking in the month between the initial telephone contact and their CARDIA examination; however, we were unable to assess this.) Perhaps the questions asked at recruitment more readily identified the "light" smokers. Indeed, a large number of the misclassified subjects were light smokers, based on their cotinine levels. Considering this explanation, it was surprising that the misclassification rate was higher when comparing cotinine levels with smoking status reported at recruitment.

Differential reporting error could explain the higher misclassification rate among Black subjects. Compared with

Whites, Blacks may underreport smoking to a greater degree because they are, in general, lighter smokers.[6] However, when the smoking status reported at recruitment (the more liberal definition) was compared with serum cotinine levels, the difference in misclassification rates between White and Black subjects persisted.

Another explanation of misclassification, also a reporting error, is denial of smoking. Study subjects may wish to report behaviors consistent with a healthy life-style. Responses received in the possibly less-threatening recruitment telephone interview support this explanation. Denial may be an important factor particularly among the former smokers, many of whom reported having quit within the past year. A desire to "kick the habit" may lead these reported former smokers to underreport their habit to the apparent marked degree noted.

Furthermore, misclassification may partially be the result of an inappropriate cotinine cutoff point. However, this does not appear to be the case; 14 ng/mL was identified as the "best" cutoff point for the overall sample. This concern is more relevant to assessing the possible cause of higher misclassification rates observed among Black subjects. Race-specific cotinine cutoff points seemed necessary because of our earlier research, which showed significantly greater cotinine levels among Black smokers than among White ones over all levels of reported nicotine exposure.[7] Furthermore, the study that originally proposed the use of a cotinine cutoff point of 14 ng/mL was conducted with a small sample of White subjects and may not be generalizable to other samples.[4] However, the race-specific cutoff points that optimized sensitivity and specificity were not considerably different from 14 ng/mL, nor did they correct the higher misclassification rates in Blacks.

Our use of self-report as the gold standard for determining the best cotinine cutoff point seems incompatible with our initial challenge of the use of questionnaire data to assess smoking prevalence. Nevertheless, a measure of internal validity suggests that self-report is reasonably valid (i.e., the smoking status of 95% of the subjects was concordant in the tobacco interview and recruitment even though some discordance was expected).

Although, in general, exposure to ETS is an unlikely explanation for misclassification, it should not be dismissed in all cases. Reported ETS exposure was significantly higher among the misclassified subjects and among Blacks. This may partially explain higher rates of misclassification among Black subjects. Differences in nicotine metabolism (i.e., longer elimination times for nicotine and its metabolites even among nonsmokers) should also be considered in further investigations of this racial difference in cotinine levels.[7,14]

In summary, these data suggest that self-report is a reasonably accurate indicator of smoking prevalence in a biracial cohort of young adults. Misclassification is more pronounced among Black subjects, former smokers, and those with a high school education or less. Higher misclassification rates among Black subjects could not be explained by the choice of a cotinine cutoff point; however, reporting errors may account for higher misclassification rates among the former smokers and the less educated. Although we identified slightly different race-specific cutoff points than the previously proposed cutoff point of 14 ng/mL, these points had little effect on our findings. □

A Prospective Study of the Attributable Risk of Cancer Due to Cigarette Smoking

Po-Huang Chyou, PhD, Abraham M. Y. Nomura, MD, and Grant N. Stemmermann, MD

ABSTRACT

Background. The goals of this study were to measure the impact of cigarette smoking on cancer incidence and to determine the attributable risk of cancer due to smoking.

Methods. A cigarette smoking history was obtained from 8006 Japanese-American men examined from 1965 through 1968. After 22 years, 1389 incident cases of cancer were identified. There were 212 men with lung cancer; 202 with oral, esophageal, laryngeal, pancreatic, renal, ureteral, or bladder (oral–bladder) cancer; and 975 with cancer at other sites.

Results. Current smokers at time of examination had a higher incidence than nonsmokers for each of the three cancer site categories. Eighty-five percent of lung cancer cases diagnosed among current and never smokers can be attributed to cigarette smoking. The attributable risks were 46%, 16%, and 29%, respectively, for oral–bladder cancers, other cancers, and all cancers combined. In turn, the corresponding attributable risks were 60%, 26%, 13%, and 21% in comparing current smokers with past smokers.

Conclusions. Current smokers can greatly reduce their risk of cancer, especially lung cancer, if they quit smoking. (*Am J Public Health.* 1992;82:37–40)

Introduction

Cancer is the second leading cause of death in the United States. It was estimated, for 1991, that more than 1 million new cancer cases and 514 000 cancer deaths would occur in the country.[1] The surgeon general of the US Public Health Service has reported that cigarette smoking is a major cause of cancer mortality in the US population.[2]

Eight large prospective studies in five countries have provided much of the information on the association between tobacco and cancer.[3–10] These mortality studies have consistently reported that cigarette smoking increases the risk of cancer deaths, especially lung cancer. They also have found that cigarette smoking leads to oral, laryngeal, and esophageal cancer and is associated with cancer of the pancreas, urinary bladder, and kidney.[2]

None of these prospective studies reported results on the incidence of cancer and the attributable risk associated with cigarette smoking. Because some subjects afflicted with cancer do not succumb to their disease, it is also important to study the impact of smoking on cancer incidence. We had the opportunity to determine the association of cancer incidence with cigarette smoking in a large cohort of 8006 men and to compute the attributable risk due to cigarette smoking. The attributable risk provides an estimate of the extent to which the excess cancer risk might be reduced if cigarette smoking were discontinued or not initiated in a study population.

Methods

American men of Japanese ancestry, born in the years 1900 through 1919 and living on the Hawaiian island of Oahu, were identified by the Honolulu Heart Program in 1965.[11] Of the 11 148 identified men, 8006 (71.8%) were interviewed and examined between 1965 and 1968, 180 (1.6%) died before they could be examined, and 2962 (26.6%) did not participate in the program. Of the 8006 men examined, the following were excluded from this analysis: 81 men with prevalent cases of cancer, 164 men with a diagnosis of cancer not confirmed by histology, and 1 subject in whom the smoking status was unknown. A total of 7760 men remained.

During the interview, information on cigarette smoking was obtained. Current smokers recorded the usual number of cigarettes smoked per day and the number of years they had smoked. Past smokers recorded the age they started smoking, the maximum number of cigarettes smoked per day, the number of years smoked, and the age they stopped smoking.

Since examination, newly diagnosed cases of cancer have been identified through continuous surveillance of all general hospitals on Oahu. From time of examination to May 1990, the study identified 1389 incident cancer cases (*International Classification of Diseases*, 8th version, codes 140–209) with tissue confirmation of their diagnosis. There were 212 men with lung cancer (code 162.1); 104 with renal, ureteral, or bladder cancer (codes 189 and 188); 35 with pan-

TABLE 1—Percentage of Smokers and Nonsmokers by Age Groups

Age at Exam	Smoking Status at Time of Interview: Never No.	Never %	Past No.	Past %	Current No.	Current %	Total
45–49	476	26.1	475	26.0	876	47.9	1827
50–54	825	30.3	667	24.5	1229	45.2	2721
55–59	497	32.3	423	27.5	617	40.2	1537
60–64	423	33.4	341	26.9	504	39.7	1268
65+	123	30.2	125	30.7	159	39.1	407
Total	2344	30.2	2031	26.2	3385	43.6	7760

creatic cancer (code 157); 25 with esophageal cancer (code 150); 24 with laryngeal cancer (code 161); 14 with oral-cavity cancer (codes 140–146); and 975 with cancer at other sites.

On the basis of a separate 19-year follow-up survey of the study subjects since their examination, we found that only 1.3% of the men could not be located on Oahu. However, these men were kept in the study because some of them could still be hospitalized on Oahu later even if they had left the island, and others could still be on Oahu even though their whereabouts were unknown.

The lung cancer cases were analyzed separately, while other cancers that have been related to cigarette smoking were combined because of their smaller numbers. These included cancer of the oral cavity, larynx, esophagus, pancreas, kidney, ureter, and bladder. They were designated as oral–bladder cancers for ease of presentation.

Site-specific and total cancer incidence rates for never, past, and current smokers were adjusted for age at examination via the direct method of standardization, with the entire cohort serving as the reference population. The reference population is the same as the one used to provide age standardization. The relative risks (RR) and 95% confidence intervals for the above cancers associated with cigarette smoking were derived from Cox's proportional hazards regression models[12] while adjusting for age at exam. Separate likelihood ratio tests were performed to evaluate the linear trend associations between cancer risks for each site and current smoking in pack-years (treated as a continuous variable).

To determine the percentage of cancer risk attributable to smoking among current and never smokers, we calculated the population attributable risk (AR) using Bruzzi's method[13] with adjustment for age. The estimated AR is similar to the incidence–density fraction of Greenland and Robins.[14] Similar analysis was done for current smokers compared with past smokers.

Results

Table 1 shows the percentage of current, past, and never smokers by 5-year age groups. The percentage of current smokers decreased with age.

The age-adjusted incidence rates and relative risks for specific cancers and all cancers by smoking status are presented in Table 2. The rates for past smokers were consistently higher than those of nonsmokers. However, the highest rates were found among current smokers. The increase in relative risk among current smokers was statistically significant ($P < .05$) for each comparison with nonsmokers.

Table 3 gives the age-adjusted relative risk of cancer by site for current smokers according to their pack-years of cigarette smoking. There was a significantly positive trend for each site by increasing amount of cigarette use. The relative risk of lung cancer was 23.3 for those who had smoked more than 45 pack-years.

The age-adjusted attributable risks of cancer for current smokers at time of interview compared with nonsmokers and past smokers are presented in Table 4. With adjustment for age, 85% of the total number of lung cancer cases among current and never smokers can be attributed to cigarette smoking. The attributable risks were 46%, 16%, and 29%, respectively, for oral–bladder cancers, other cancers, and all cancers combined. In turn, 60% of the total number of lung cancers among current and past smokers can be attributed to the persistence in smoking. The attributable risks were, correspondingly, 26% for oral–bladder cancers, 13% for other cancers, and 21% for all cancers.

Discussion

All Cancers

The incidence data in this study showed that current and past smokers at time of interview had a significantly greater risk for all cancers than their nonsmoking counterparts. The observed relative risks were 1.9 for current smokers and 1.2 for past smokers. These results were similar to those of cancer mortality studies that found that the overall cancer mortality risks ranged from 1.7 to 2.6 for current cigarette smokers and from 1.4 to 1.5 for past smokers.[5,15,16]

A principal observation in this study is that 29% of total cancer risk among current and never smokers can be attributed to cigarette smoking. It was also observed that total cancer risk among smokers could be reduced by 21% if current smokers became past smokers, as shown in Table 4. These data are encouraging and suggest that the cessation of cigarette smoking can reduce the risk of cancer. The 1982 surgeon general's report noted that smoking contributed to 43% of all US male cancer deaths.[2] However, the report neither separated the effect among current and past smokers nor adjusted for age. If current and past smokers are combined in our study, 26% of all incident cancer cases can be attributed to cigarette smoking.

Lung Cancer

Lung cancer is the site with the highest relative risk due to cigarette smoking. Current smokers at time of interview had a relative risk of 12, while a threefold increase in risk for lung cancer was also observed for past smokers. In addition, a strong dose–response trend was observed with increasing number of pack-years among current smokers.

Our findings are similar to those of the 16-year follow-up study of US veterans.[5] It reported that the mortality ratios for lung cancer were 11.3 for current smokers and 4.0 for past smokers. Seven other prospective studies[3,4,6–10] and three case–control studies[17–19] showed a consistently positive pattern between cigarette smoking and lung cancer, with a relative risk up to 14.2 in the Canadian Veterans Study.[6]

Our study observed that 85% of lung cancer incidence among current and never smokers could have been avoided if current smokers had never smoked cigarettes. If current smokers had ceased smoking, 60% of the lung cancer risk that occurred within the population of current

and past smokers could have been avoided. For smokers in a case–control study in Louisiana, 90% of the lung cancer risk was attributable to active cigarette smoking.[19] The 1982 surgeon general's report estimated that 91% of lung cancer deaths were attributable to the effects of smoking.[2]

Oral–Bladder Cancers

The risk of oral–bladder cancers among current smokers at time of interview was significantly elevated in this study. An accentuation in risk was observed with increasing number of pack-years of cigarette smoking among current smokers.

Wynder et al. have noted that smoking-related cancers in men include cancer of the mouth, larynx, esophagus, pancreas, and bladder, in addition to the lung.[20] In four earlier studies,[3,15,21,22] the mortality risks for the combination of oral, pharyngeal, laryngeal, and esophageal cancer ranged from 2.2 to 7.0 for smokers compared with nonsmokers. Other studies have reported results separately for cancer of the pancreas,[5,22–26] bladder,[5,22,26–28] and kidney.[5,22,29] The risks for these cancers ranged from 1.4 to 5.4 for current smokers, 1.2 to 1.6 for past smokers, and 1.4 to 2.7 for smokers as a group, compared with nonsmokers.

TABLE 4—Age-adjusted Attributable Risks for Specific Cancers and All Cancers for Current Smokers at Time of Interview Compared with Never Smokers and Past Smokers

Cancer Site	Current Smokers vs Never Smokers (%)	Current Smokers vs Past Smokers (%)
Lung	85	60
Oral–bladder[a]	46	26
Other	16	13
All	29	21

[a]Cancer of the oral cavity, larynx, esophagus, pancreas, kidney, ureter, or bladder.

The 1982 surgeon general's report noted that the percentages of death among US males possibly due to smoking were 75% for mouth, pharyngeal, laryngeal, or esophageal cancer; 56% for bladder cancer; and 40% for pancreatic cancer. Our findings showed that 46% of the incidence due to oral–bladder cancers among current and never smokers could be avoided if current smokers had never smoked. Alternatively, if they give up smoking, their excess risk for these cancers could be reduced by 26%.

Other Cancers

Current smokers had a modest risk (RR = 1.5) for other cancers in the study. A positive trend in risk with increasing pack-years of smoking among current smokers was also noted, but the dose–response trend was not linear. If there is a true increase in risk of other cancers due to cigarette smoking, it is not as substan-

tial as that for lung and oral–bladder cancers. The data suggest that up to 16% of the incidence of other cancers among current and never smokers could be avoided if current smokers had never smoked.

Limitations of the Study

The assumption was made in this study that a person's smoking status at time of interview would remain the same throughout the follow-up period. Other studies,[3,5] however, have indicated that some men who reported themselves as current cigarette smokers at the beginning of the study had stopped smoking during the course of the study. Consequently, the group of current smokers included an appreciable proportion of ex-cigarette smokers. If such misclassifications/biases existed in our study, the reported risks of cancer for current smokers would probably be underestimated, suggesting that the actual benefits of smoking cessation could be greater than those shown. It is very unlikely that nonsmoking subjects, who were 45 through 68 years of age at time of interview, started smoking during the course of the study.

Conclusion

The present study provides cancer incidence data consistent with past cancer mortality data of the harmful effects of cigarette smoking. Evidence is especially overwhelming on the association between current cigarette smoking and the risk of lung cancer. An effective way of reducing the risk of cancer associated with cigarette smoking is to quit smoking, as shown by the data on attributable risk. Development of smoking-cessation programs that would enable current smokers to permanently quit their cigarette habit within the shortest time period should be strongly supported. □

Brief Supportive Telephone Outreach as a Recruitment and Intervention Strategy for Smoking Cessation

Harry A. Lando, PhD, Wendy L. Hellerstedt, MPH, Phyllis L. Pirie, PhD, and Paul G. McGovern, PhD

ABSTRACT

Background. Formal efforts to recruit smokers into cessation programs have failed to reach large segments of the smoking population. Telephone intervention may represent a viable strategy to promote smoking cessation. An even more promising approach may be a combination of brief telephone support and outreach to identified smokers.

Methods. Telephone support for smoking cessation was provided to four identified smoker populations in Bloomington, Minn, one of three Minnesota Heart Health Program education communities. Smokers were randomly assigned to an intervention consisting of two 15-minute telephone calls approximately 1 to 3 weeks apart or to a nonintervention control.

Results. At the 6-month follow-up, a significant overall effect was found in favor of the intervention condition for both self-reported and cotinine-validated quitting. Differences between intervention and control conditions were no longer significant at 18 months.

Conclusions. Smokers' receptivity to telephone intervention was at least moderately encouraging. The cost of intervention could be relatively low if trained volunteers initiated telephone calls. However, more intensive telephone intervention and support may be needed to produce lasting changes in smoking prevalence. (*Am J Public Health.* 1992; 82:41–46)

Introduction

Formal efforts to recruit smokers into cessation programs have failed to reach large segments of the smoking population.[1,2] Although the vast majority of smokers express a desire to quit, they also state a preference to quit on their own.[1,3] Indeed, the vast majority of smokers who quit do so without formal assistance.[4] Unfortunately, individual unaided quit attempts tend to have a low long-term success rate; reports indicate that fewer than 10% of those who quit on their own maintain abstinence for one year.[5,6]

Telephone intervention may represent a viable strategy to promote smoking cessation. Such intervention is distinct from telephone help lines, which function less as proactive interventions than as resources for a relatively small proportion of smokers who seek them out for support.[7] A more promising use of the telephone has been demonstrated.[8–10] Orleans and her colleagues[8] found that a combination of self-help materials and minimal telephone support resulted in 6-month continuous abstinence rates at 16 months that clearly favored telephone support over self-help materials alone.

An even more promising approach may be a combination of brief telephone support and outreach to identified smokers. Such an outreach strategy may be a cost-effective means of reaching large proportions of smokers. Lando et al.[11] were successful in recruiting 70% of an identified population of smokers to participate in a study evaluating the effectiveness of self-help quit materials. Overall outcomes were comparable to those obtained in a number of other evaluations of self-help in which participants were self-referred volunteers.[12–14]

In the present study we assessed brief telephone outreach as a recruitment and intervention tool. Intervention took place in Bloomington, Minn, one of the three education communities in the Minnesota Heart Health Program (MHHP), a 10-year research and demonstration project intended to reduce cardiovascular disease risk.[15] At the time of the present study, intervention in Bloomington had been going on for almost 5 years. The selection of Bloomington permitted relatively easy access to a large identified population of smokers.

Four discrete smoker populations were studied. The groups included current registrants in an extended community quit-smoking contest, previous MHHP smoking class or contest participants, and smokers who were identified at an initial heart health screening but who had never participated in MHHP smoking cessation activities. Over 60% of the overall Bloomington population and approximately 44% of Bloomington smokers had taken part in heart health screenings. The fourth group, Bloomington residents who had not attended this screening or any other MHHP activity, had been identified through an earlier telephone survey. Smokers in this survey who expressed interest in quitting were eligible for intervention.

[a]Subjects who reported quitting prior to the intervention (n = 264) are included here as part of the original pool. However, these subjects were excluded from all analyses.
[b]Subjects who denied smoking more than 100 cigarettes in their lifetime (n = 16) at 6 months were not contacted at 18 months.

For each of the smoker populations, a supportive telephone outreach intervention was compared against a nonintervention control. In each case it was hypothesized that those assigned to telephone support would achieve a higher rate of quit attempts and long-term abstinence than would control subjects. It was further hypothesized that abstinence levels would be highest among current contest participants, followed by previous class or contest participants, and then by participants in screening who had not attended smoking cessation programs. No prediction of relative outcome was attempted for those who had not participated in MHHP activities or screening.

Methods

Subjects

Four mutually exclusive populations were included (Table 1).

Quit Date '83 registrants. The 859 subjects in this group had registered for an extended quit-smoking contest (Quit Date '88) that was offered in Bloomington from June 1988 through January 1989.[16-18] The subjects were further categorized by whether they pledged to quit on a specific date after entering the contest.

Recyclers. The 895 subjects in this group were identified from MHHP lists of former quit-smoking class or contest participants.

Heart health screenees. This group of 4562 subjects had identified themselves as smokers at heart health screenings up to 4 years earlier, but had not participated in MHHP smoking cessation activities. MHHP screening included assessment of the targeted risk factors: cholesterol, hypertension, obesity and eating habits, and smoking status.[15]

Nonparticipants in MHHP screenings and programs. A group of 410 smokers was identified from a total of 5642 telephone numbers. These numbers, randomly generated to represent a community population sample, did not appear on any list of MHHP participants. After these numbers were randomized to intervention and control conditions, a telephone survey was conducted. From this survey 4595 telephone numbers were identified as ineligible because they were incorrect or were business numbers or because no age-eligible smokers permanently resided in the household. A total of 1229 eligible smokers (between the ages of 25 and 74) were identified in 1047 households. Of these eligible smokers, 875 (71%) agreed to complete the telephone survey. Respondents were asked if they would be receptive to a subsequent telephone call that would offer them information on materials, classes, and methods to help them quit smoking. The 461 respondents (53% of those who completed the telephone survey; 37.5% of all eligible smokers identified) who expressed interest in this subsequent call were therefore eligible to participate in the study. Because of concern about the clustering of smoking behavior within households and the effects of subject interdependence on the analyses, only one smoker was randomly selected per household; thus 410 smokers were available for the study. (Randomization to intervention and follow-up.)

Of the total of 6777 smokers in these four populations, 4655 were randomized to intervention and 2122 to control. Among the 4655 smokers randomized to intervention, 1393 could not be reached. It is assumed that a majority of these were wrong numbers and thus ineligible. Smokers were also considered ineligible if they moved from Bloomington. Of the eligible 3262, only 65 (2%) refused to speak to the interventionist. A total of 813 persons had already quit smoking but remained in the intervention, which included a maintenance protocol. This left a pool of 2384 smokers. Those assigned to the control condition were not contacted prior to follow-up.

A smaller sample of 937 intervention and 890 control subjects was randomly selected for postintervention telephone follow-up at 6 and 18 months. At 6 months, 1733 (95%) of the 1827 subjects were contacted. At 18 months, follow-up was complete for 855 intervention and 808 control subjects, representing response rates of 91% for each group. Subjects who reported at the 6-month follow-up that they quit smoking prior to the intervention (n = 264) or who denied ever smoking more than 100 cigarettes in their lifetime (n = 16) were excluded from the analyses because the focus of the study was intervention effects on current smokers. Thus, 1453 (80%) of the 1827 subjects were classified as smokers at the time of the intervention and were included in the outcome analyses at 6 months; 1399 (77%) were available for the 18-month analysis. The 16 subjects who denied ever smoking more than 100 cigarettes, were not recontacted at 18 months.

Telephone Interventionists

Lay telephone interventionists included 15 women and 2 men ranging in age from 18 to 65 years. Ten interventionists had college degrees; seven had no college degrees but had previous telephone interviewing experience in the Division of Epidemiology.

Interventionists received 5 hours of training in smoking cessation techniques

and were also given individual reading assignments addressing health issues relating to smoking, benefits of smoking cessation, smoking cessation techniques, commonly asked questions pertaining to smoking, community resources dedicated to smoking cessation, and methods of supporting quit attempts. They were required to satisfactorily perform role plays of intervention calls and to make several calls to pilot subjects prior to telephoning actual study participants. A reference manual on cessation and maintenance strategies based on the MHHP *Quit and Win* self-help guide[19] was provided for their use in completing calls. A supervisor carefully monitored telephone calls, especially during the first few days of intervention. Weekly staff meetings were held to review progress and problems.

Procedure

Telephone calls were placed between 5 PM and 9 PM Sunday through Friday and between 9:30 AM and 1:30 PM on Saturday. Although a standard script was used for telephoning, the script allowed interventionists considerable latitude in talking to subjects. Interventionists introduced themselves and indicated that they were calling on behalf of the Bloomington Heart Health Program.

Current smokers were queried concerning their interest in quitting. Those who expressed interest were encouraged to initiate concrete steps toward cessation. The interventionist worked with the subject to identify possible barriers to cessation and methods by which these barriers could be minimized. Emphasis was placed upon the use of appropriate coping strategies to resist urges to smoke. Subjects who identified themselves as ex-smokers were congratulated and were asked if they had any questions about maintenance. They were offered a free maintenance guide and the telephone number of a smokers help line.

A major goal of the telephone intervention was to lead smokers to establish a specific target date for quitting. Subjects were offered free self-help materials based on the *Quit and Win* manual.[19] In addition, available help options were discussed, including Quit Date '88 (for individuals who were not already enrolled) and the community telephone help line service. Smokers were also given certificates that allowed them to enroll at no cost in a clinic program that was being offered to the general public for $95. Even if subjects were not prepared to set a quit date, they were urged to take concrete action toward quitting (e.g., cutting down on number of cigarettes, switching to a lower tar and nicotine brand).

All subjects were asked to consent to a second call within 2 to 3 weeks. For subjects who set a quit date, the second call was completed within 1 week after that date whenever possible. Subjects who had quit were congratulated and any difficulties were discussed. Those who had not initially set a date were again encouraged to do so. Subjects who had not quit or who were experiencing difficulties were reminded again of community resources. In both calls, the interventionist emphasized the identification, use, and modification of personally relevant coping strategies. First and second calls averaged less than 15 minutes each and were usually made by the same interventionist. Subjects were not offered the option of a third call. (A more detailed telephone intervention protocol is available on request from the first author.)

Follow-up Assessment

Telephone follow-up surveys at 6 and 18 months after the telephone intervention assessed basic demographic and smoking history data (at 6 months only), participation in cessation activities, information on quit attempts, and current smoking status. The surveys were administered by trained interviewers for the Telephone Survey Center in the Division of Epidemiology at the University of Minnesota. All subjects were asked, "Do you smoke cigarettes at present?" Those who said "no" at 6 months and who reported quitting after the intervention were scheduled for home visits to collect saliva samples for cotinine analysis. The mean interval between the telephone survey and saliva collection was 8 days; all samples were gathered within 15 days of the survey. No biochemical validations were performed at 18 months. Cotinine analyses were performed in the Division of Epidemiology.

Results

Initial Response to the Telephone Intervention

Of the 2449 smokers in the four intervention groups, 2384 (97%) received the intervention call and 75% requested the self-help smoking cessation materials offered by the interventionist. Seventy percent of the smokers consented to a second telephone call. Of those not already enrolled in Quit Date '88, 34.7% expressed interest in signing up for the contest in response to the telephone intervention. However, only 15% of the subjects committed to a specific quit date at the time of the initial telephone call. Among those who received a second call, 7.1% reported having quit, and an additional 14.6% reported having made a quit attempt since the first call.

Subject Characteristics

The 1399 subjects (intervention and control) available at 18 months included 703 women and 696 men. Demographic characteristics of the subjects are presented in Table 2. The mean age at which the subjects started smoking was 19 years. Their average age was 46.5 years. The subjects were asked about their current cigarette consumption or their cigarette consumption immediately prior to quitting. The average number of cigarettes smoked per day was 22. There were no significant differences between intervention and control subjects in demographic and smoking history characteristics. Generally, differences within the four subpopulations of smokers also were nonsignificant.

Quit attempts. Among current smokers, there were few differences in number of reported quit attempts (a minimum of 24 hours of abstinence) between intervention and control subjects or between the four smoker populations. This was true at both the 6-month follow-up and the 18-month follow-up.

Six-month abstinence. At the 6-month follow-up, a significant overall effect was found in favor of the intervention condition for both self-reported and cotinine-validated abstinence (Table 3). Overall self-reported abstinence rates at the time of the 6-month interview were 12% for intervention subjects and 8% for control subjects, $\chi^2(1) = 6.713$, $P = .009$. However, a substantial number of subjects (24%) refused to undergo cotinine validation. Of those who agreed, 45% exceeded the validation cutoff of 10 ng/mL. Saliva thiocyanate analyses were also available and were generally consistent with the results for cotinine. Thiocyanate levels exceeded 100 μmol/L (the recommended cutoff for validation) for 76% of those with cotinine levels greater than 10 ng/mL. Thus, validated 6-month abstinence rates were 5.48% for intervention subjects and 2.55% for control subjects, $\chi^2(1) = 8.018$, $P = .005$. Those who refused to undergo validation and individuals who were not contacted were classified as smokers for the purposes of data analysis.

[b]Cotinine ≤10.

Although trends were in the expected direction within each of the four population groups, differences between the intervention and control groups were significant only for previous class or contest participants (recyclers). In this population, the self-reported abstinence rate at 6 months was 13.2% among intervention subjects, as opposed to only 5.7% for control subjects, $\chi^2(1) = 4.698$, $P = .03$. Again, however, validated abstinence rates were considerably lower: 7.6% for intervention subjects and 1.4% for control subjects, $\chi^2(1) = 6.33$, $P = .012$.

Eighteen-month abstinence. Differences between intervention and control subjects were no longer significant at the 18-month follow-up, either overall or for any of the separate smoker populations (see Table 3).

Continuous abstinence. Continuous abstinence was also examined at both the 6-month and 18-month follow-ups. Continuous abstinence was considered in three categories: validated at 6 months, self-reported at 6 months, and self-reported at 18 months. In all categories, the quit date had to be at least 3 months prior to the interview. Table 4 shows the number of subjects within each of these categories who reported "no puff" since quitting and no relapse lasting more than 6 days since quitting. Overall differences again favored the intervention condition at 6 months but not at 18 months. Differences were not significant within the four separate population groups. Overall, at the 6-month follow-up, validated 3-month continuous abstinence rates were 4.5% for intervention subjects and 2.1% for controls, $\chi^2(1) = 6.44$, $P = .01$. The most stringent criterion (6 months' continuous abstinence, not even a puff) yielded slightly lower abstinence rates: 3.8% for intervention subjects and 2.1% for controls, $\chi^2(1) = 3.64$, $P = .056$. As with point prevalence data smoking status at the time of follow-up, self-reported continuous abstinence rates were considerably higher than were cotinine-validated abstinence rates.

Consistent with the point prevalence data, overall 18-month self-reported continuous abstinence rates did not differ between intervention and control groups. However, when only that subset of subjects was considered who achieved at least 3 months of continuous self-reported and validated abstinence by the 6-month follow-up, differences at 18 months continued to favor the intervention condition.

Discussion

The initial results of the present study were moderately encouraging. Two brief telephone calls were sufficient to produce overall differences in outcome between intervention and control subjects at the

6-month follow-up. The success of this brief and potentially generalizable intervention in substantially increasing quitting rates among previous class or contest participants at that point is a positive finding. These results suggest that those who have enrolled in formal quit programs or contests may be receptive to further intervention despite the fact that they are likely to be hard-core smokers.[1] However, the overall cotinine-validated quit rate of less than 6% for intervention subjects at 6 months is modest.

The rather dramatic differences between self-reported and cotinine-validated abstinence rates were unexpected.[20,21] In addition to this high level of disconfirmation, more than one quarter of the subjects refused to undergo cotinine validation. All of these subjects were classified as smokers for the purposes of data analysis. This classification may be a bit conservative, however. Several of those who refused objected to the intrusiveness of the saliva collection procedure. Others expressed a fear of contracting AIDS as a result of providing a saliva sample. An increasing refusal rate for saliva collection has been noted elsewhere.[11]

Unfortunately, overall treatment effects were no longer evident at the 18-month follow-up. Somewhat encouraging is the fact that among subjects who had achieved at least 3 months of continuous abstinence by the 6-month follow-up, 18-month results continued to favor the intervention condition. Self-reported abstinence rates were higher overall at 18 months than at 6 months. This might have suggested a delayed impact of intervention,[13] except for the fact that abstinence rates actually tended to show greater improvement in control subjects over this time period. The 16% self-reported abstinence rate among control subjects at 18 months was surprisingly high, but self-reported quit rates are likely to have been inflated by false reporting. Number of quit attempts did not differ significantly between intervention and control subjects (although trends at the 6-month follow-up were in the expected direction).

Although the overall results were modest, the receptivity of smokers to the telephone intervention is a positive finding of this study. Previous studies have indicated that the vast majority of smokers are not interested in formal face-to-face interventions.[1,22] In the present study, 75% of intervention subjects accepted self-help materials and 70% agreed to a second telephone call. The level of responsiveness among the one group specifically recruited for the intervention—the non-MHHP participants—was especially gratifying. More than half of those interviewed not only expressed interest in quitting but agreed to receive intervention telephone calls. On the other hand, only 15% of all intervention subjects committed to a specific quit date at the time of the initial telephone call. Even so, respondents' acceptance of intervention offered through "cold" telephone contact suggests that telephone outreach procedures may be a useful channel for increasing the proportion of smokers recruited into treatment.

The demographic characteristics of the study participants support the ability of this intervention to reach individuals who are not typical participants in formal treatment programs. Over one third of all subjects reported a high school education or less. More than 40% worked in clerical positions and an additional 19% were not employed. In contrast to most formal programs, which tend to attract a more highly educated and professional clientele, the participants in this study were broadly representative of the larger Bloomington smoker population.

The cost of intervention could be relatively low if trained volunteers initiated telephone calls to identified populations of smokers. An organization such as the American Lung Association could provide additional telephone support and encouragement to individuals who had previously enrolled in its Freedom from Smoking clinics, for example. Communities could provide telephone support to smokers enrolled in local quit-smoking contests. Volunteer telephoners could be recent ex-smokers, whose support of others would reinforce their own efforts to remain abstinent. Telephone intervention is highly portable and could be used to reach individuals in remote locations.

The study population was drawn from a community that received multiyear heart disease prevention programming, thus raising questions about the study's generalizability. Furthermore, this community is located in Minnesota, a state that has been in the forefront of tobacco control activities for over a decade. These circumstances may have enhanced residents' responsiveness to any effort to change health behavior, including the current smoking cessation intervention. On the other hand, Bloomington residents may have experienced overexposure to MHHP intervention, and therefore may be resistant to undertaking further changes in their health behaviors.[18] National efforts supporting individual and

cultural changes in life-style–related education and social norms appear to be accelerating, especially with regard to smoking. The MHHP environment reflects what conceivably could become the norm in many parts of the nation.

The high degree of receptivity among the subjects and the positive initial results suggest that telephone intervention strategies are worth pursuing. At this point the challenge is to improve long-term maintenance. Future research should address the possible gain in efficacy versus the additional costs of more extended telephone support. If supportive telephone outreach strategies are replicable and can produce significant intervention effects, they may have important implications not only for smoking but for other life-style–related public health problems. □

Adolescent Smoking, Weight Changes, and Binge-Purge Behavior: Associations with Secondary Amenorrhea

Jim Johnson, PhD, and Agnes H. Whitaker, MD

ABSTRACT

Background. The association of secondary amenorrhea with extreme forms of substance use, weight control, and exercise in nonrepresentative samples raises questions as to whether adolescents in the general population who engage in these behaviors are at increased risk for secondary amenorrhea. We examined the prevalence and behavioral correlates of secondary amenorrhea in a county-wide high school population of 2544 girls aged 13 to 18.

Methods. A survey questionnaire, which elicited menstrual history as well as weight history, weight control practices, level of exercise, and use of cigarettes, wine, and beer, was administered during school hours; absentees were also surveyed. The completion rate was 91%.

Results. The 1-year prevalence of secondary amenorrhea was 8.5%. Secondary amenorrhea was associated with smoking one or more packs of cigarettes per day (adjusted relative risk [RRa] = 1.96, 1.21–3.10), with multiple binge-eating behaviors in combination with laxative use or self-induced vomiting (RRa = 4.17, 2.54–6.32), and with weight fluctuation due to weight control (RRa = 2.59, 1.33–4.79). There was no association between amenorrhea and alcohol consumption or exercise level.

Conclusions. Estimates of attributable risk are provided and indicate that bulimic behaviors and cigarette smoking may result in a considerable excess of cases of secondary amenorrhea in an adolescent population. (*Am J Public Health.* 1992;82:47–54)

Introduction

There is a striking paucity of data on the epidemiology and correlates of amenorrhea among adolescent females. The few studies that have examined menstruation among community-based samples of adolescent females have restricted their focus to age at menarche[1–4] and to other menstrual characteristics, such as oligomenorrhea[1] and dysmenorrhea.[1,5] In recent years, clinical research on amenorrhea has also focused on nonpregnant clinical samples with high rates of amenorrhea. In addition to patients with well-defined medical disorders,[6,7] these samples include patients with eating disorders, such as anorexia nervosa[8–10] and bulimia,[11–16] and substance abuse disorders, such as alcoholism.[17] High rates of amenorrhea have also been found in career ballet dancers[18,19] and athletes.[20–22]

The association of amenorrhea with extreme forms of weight control, substance use, and exercise in these highly nonrepresentative samples raises the question of whether adolescents in the general population who engage in these behaviors are at increased risk for secondary amenorrhea. The importance of the question is underscored by two sets of findings: (1) the high rates at which adolescent girls experiment with weight control,[23] cigarettes,[24,25] and alcohol;[25,26] and (2) the association of amenorrhea in selected samples with increased rates of infertility,[27] increased rates of osteoporosis,[28,29] scoliosis and stress fractures,[30,31] and lower lifetime occurrence of breast cancer and cancers of the reproductive system[32]—all conditions of major concern to women.

Amenorrhea is classified for clinical purposes as either primary or secondary. Primary amenorrhea is defined as the failure to achieve menarche by age 16.[6,7] Secondary amenorrhea refers to the prolonged absence (usually defined as 3 months) of menstrual bleeding any time after menarche.[6,7] These age and duration guidelines for the clinical investigation of adolescent amenorrhea take into account the normal variation in age of menarche (11 to 15 years)[2] and the physiological occurrence of irregular intermenstrual intervals (oligomenorrhea) due to anovulatory cycles in the first years after menarche.[1,33–35] Amenorrhea is properly regarded as a symptom that may reflect quite different etiologies and endocrine profiles.

This study focuses on the prevalence and behavioral correlates of secondary amenorrhea in an unselected population of adolescent females.

Methods

Study Sample and Measures

The study sample was a county-wide population of high school students (n = 5596) who participated in a survey of selected psychiatric disorders in 1985.[23] Students were surveyed during classroom hours in the eight high schools in the county (five general public schools, one vocational public school, one independent

day and boarding school, and one parochial day school). The study protocol included provision for surveying absentees. Of the county-wide enrollment, 91% (2564 boys and 2544 girls) returned valid questionnaires. The population was primarily White (94 percent) and was evenly distributed across ages 14 to 17; 2.5% were 13 years old or younger, and 5.5% were 18 years old or older.

The girls' version of the survey questionnaire asked whether menstrual periods had begun and, if so, the year and month of menarche. Postmenarchal girls were asked, "Have you missed three of your expected periods in a row since this time last year?" Other menstrual questions, with the exception of the item concerning amenorrhea, were patterned after the questionnaire items of Widholm and Kantero.[1] Other investigators have found that adolescents report age at menarche with a high degree of accuracy.[36]

Weight control practices, binge-eating, and weight history were assessed with the Eating Symptoms Inventory.[23] This instrument contains 24 sets of questions that operationalize the symptoms of anorexia nervosa and bulimia as defined by the American Psychiatric Association in *the Diagnostic and Statistical Manual of Mental Disorders* (3rd ed.) (*DSM-III*).[37] Binge-eating behaviors included large binges, recurrent binges, and binge discomfort (termination of binges for abdominal pain, sleep, social interruption, or feeling the urge to throw up), as detailed in an earlier report.[23] Dieting, fasting, purging (self-induced vomiting and laxative use), and use of diet pills and diuretics were also assessed. From a review of semistructured clinical interviews with a subsample of 356 students who participated in the survey, a screen for eating disorders based on items in the inventory and on the Diet Factor from the Eating Attitudes Test[38] identified cases of anorexia nervosa and bulimia with a sensitivity of 86.7 and a specificity of 72.9.[39]

Level of exercise was assessed by listing nine types of activities and asking how many days per week in the past month the student engaged in those activities. Cigarette use and beer and wine consumption were assessed with items drawn from Kandel.[40] Other studies have found that adolescent self-reports on cigarette[41] and alcohol use are valid.[42,43] To our knowledge, the validity of adolescent reports on exercise has not been studied.

As for background characteristics, social class was defined according to Hollingshead,[44] relative body weight was defined by body mass index (BMI) (weight in kg/height in $cm^2 \times 10\,000$),[45,46] and gynecologic age was defined as the difference in years between chronological age and age at menarche.[47,48] Accuracy of students' reports of height and weight were assessed with a validity study.[23] Reports for height were found to be accurate and unbiased whereas heavy girls tended to underestimate their weight; however, the bias was minimal (~2.5 kg).

By definition, premenarchal girls were not considered to be at risk for secondary amenorrhea.

Statistical Analysis

Risks are framed in terms of relative risk (RR).[49] Problems related to interpretation of risk factors in a cross-sectional study are reserved for the discussion. We also report 95% confidence intervals (CIs) based on the limits of risk.

Most of the putative risk factors (weight history, weight control practices, substance abuse, and exercise) were to some extent correlated; any statement about independent contributions to the risk of secondary amenorrhea had to include evaluation of these potential risk factors in a multivariate logistic regression model in conjunction with careful examination of the cross-classified risks. The RRs of amenorrhea reported in Tables 1 and 2 are the ratios (proportions) of the risk in those exposed to the risk factor to the risk in those unexposed. CIs are from the limits of the probabilities of a logistic regression estimate in both the unadjusted (Table 1) and adjusted (Table 2) case. In Table 2, the estimated risk for an individual is given by

$$1/\{1 + \exp[-1*(\text{constant} + b1X1 + \ldots brXr)]\}.$$[50]

TABLE 2—Summary from Multivariate Analyses (Logistic Regression): Risk Factors for Secondary Amenorrhea among Nonreferred Adolescent Girls

Risk Factor	Exposure	Adjusted Relative Risk	95% CI	Excess Fraction for Population	Attributable Risk in Those Exposed
Smoking (≥one pack daily)	.068	1.96	(1.21–3.10)	.061	.49
(<one pack daily)	.253	1.35	(0.90–1.72)	.059	.20
Binge-purging (frequent)	.031	4.17	(2.54–6.52)	.089	.76
(infrequent)	.143	1.99	(1.39–2.81)	.124	.50
Weight loss (≥ 4.5 kg)	.103	1.45	(.95–2.20)	.044	.31
Weight gain (≥ 4.5 kg)	.222	1.71	(1.16–2.49)	.136	.42
Both loss and gain	.035	2.59	(1.33–4.79)	.053	.61
First year after menarche	.129	1.74	(1.07–2.76)	not applicable	
Age at menarche > 12.5 years	.481	1.38	(0.99–1.92)	not applicable	

Note. CI = confidence interval.

We have avoided reporting adjusted odds ratios in this cross-sectional study, given that the risk in some of the exposed strata (e.g., severe binge-purge) violates the "rare disease" assumption.[49] If one is concerned about statistical significance, the CIs reported in Tables 1 and 2 exclude one only when the odds ratio would also. To the extent that the risk in a number of the exposed groups exceeds 10%, the relative risks, as reported in Tables 1 and 2, is the superior point estimates of risk when compared with the odds ratio.

As an estimate of the adjusted population excess fraction (population attributable risk), we also use

$$p(\text{exposure})^*(1 - RRa)/$$
$$\{[p(\text{exposure})^*(RRa - 1)] + 1\}.$$

Because there is some controversy over the use of this estimate,[51,52,53] we stratified the data as far as feasible and reestimated using (1) Greenland's "exact method"[52] equation 2, and (2) Miettinen's multivariate confounder score method; the latter allowed us to do what we did in (1) while retaining more information with respect to dosage.[54] In each case, the estimates obtained by these three alternative methods were consistent within rounding error. Convergence of solutions suggests that the estimates of adjusted excess fractions (Table 2) are reasonable.

Results

Prevalence of Primary and Secondary Amenorrhea. Among girls aged 16 and older, the prevalence of primary amenorrhea (premenarchal status) was 2.0%. The 1-year prevalence of secondary amenorrhea in postmenarcheal girls was 8.5%. Only 1 out of the 245 girls subsequently interviewed by clinicians in the second stage of the study had ever been pregnant, suggesting that pregnancy at most accounted for one or two reports of secondary amenorrhea in these data. Among the 2544 girls surveyed in this semirural county, 36 reported using birth control pills, and the prevalence of secondary amenorrhea among them was 5.6% (vs 8.5% for the remainder of the population).

Relationships with Social Class, Age, and BMI. The proportion of girls who reported secondary amenorrhea in the past year appears in Table 3 by social class,[44] chronological age, gynecological age, and BMI quartile. Secondary amenorrhea was not significantly related to social class (by chi-square statistic). A post hoc grouping of the lowest two social classes (suggested by the data in Table 3) also failed to yield a significant difference. Risk of secondary amenorrhea was highest among girls whose gynecologic age was 2 years or less, and it was lower in the older gynecologic age groups.

There was no relationship between secondary amenorrhea and BMI quartile. More restricted divisions of BMI, including deciles, were also unrelated to secondary amenorrhea, as was percent below ideal weight at lowest weight for previous year.

Weight Control, Bulimic Behaviors, and Weight Changes. Girls who had dieted, even for longer than 28 consecutive days, were not at increased risk for secondary amenorrhea when compared with girls who had not. However, girls who had fasted for extended periods (3 or more days) were at some increased risk (RR = 1.84, 95% CI = 1.20–2.71) (Table 1). Duration of dieting and fasting were evaluated independently of kilograms lost on a diet or fast because many girls reported that they had dieted (or fasted) for extended periods without weight loss.[23]

In contrast to simple duration of dieting, other methods of weight control

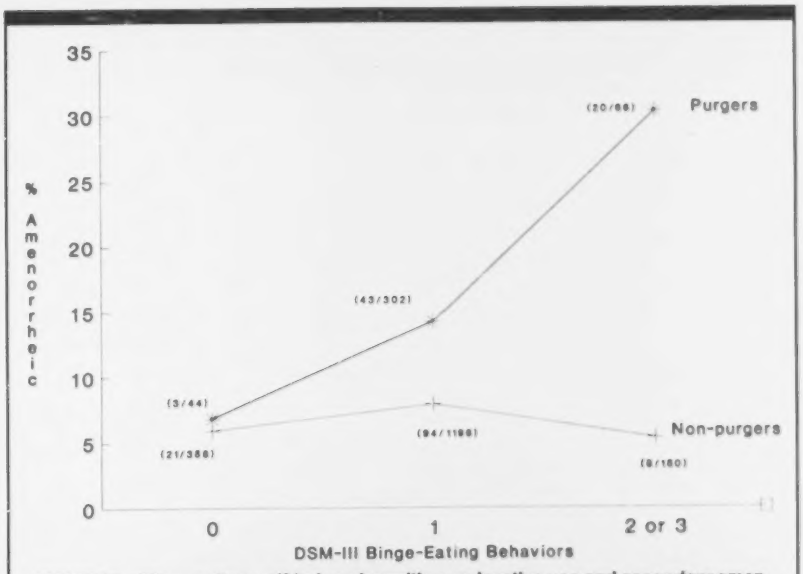

FIGURE 1—Binge eating, self-induced vomiting, or laxative use and secondary amenorrhea. Amenorrhea is defined as three consecutive missed menstrual periods in the past year in a postmenarchal girl. "Purgers" report use of self-induced vomiting or laxative for weight control. Binge-eating behaviors consist of large binges, frequent binges, and binge discomfort (see text).

were associated with higher risk for secondary amenorrhea. Self-induced vomiting, use of laxatives, and use of diet pills (mainly nonprescription) were each associated with one and one-half to threefold increases in risk for secondary amenorrhea (Table 1). The use of diuretics (nonprescription) was not significantly associated with increased risk (RR = 1.64, 95% CI = n.s.); however, the number of girls who used diuretics was small (n = 22), and thus our statistical power to detect such an increase in risk was minimal. As we have reported elsewhere,[23] weight control behaviors were more common in girls who were older and heavier (by BMI) and were minimally related to social class.

Reports of binge-eating consistent with the *DSM-III*[37] definition of this behavior were associated with a twofold increase in the risk of secondary amenorrhea.

With respect to weight change in the past year, girls who had gained at least 4.5 kg, or 10 lb, and girls whose weight had fluctuated (a gain of 4.5 kg or more combined with a loss of 4.5 kg or more) in the past year were at higher risk for secondary amenorrhea (RR = 1.93, 95% CI = 1.36–2.67; RR = 2.82, 95% CI = 1.61–4.60, respectively) when compared with girls who had not gained or lost 4.5 kg in the previous year (Table 1). Girls who reported a simple loss of at least 4.5 kg in the previous year were also at some increased risk for secondary amenorrhea (RR = 1.54, 95% CI = 1.05–2.23). However, a weight loss of 4.5 kg or more appeared to be a greater risk factor in girls in the lowest BMI quartile (RR = 3.00, 95% CI = 1.44–5.53, not shown on Table 1). For these analyses, a cutoff of 4.5 kg or more was used to evaluate weight change as a risk factor. Parallel analyses using number of kilograms lost, percent of body weight lost, or various transformations (e.g., log (kg)) produced similar results.

Exercise Regimens. Girls who exercised daily were not at greater risk for premenarchal status or secondary amenorrhea than those who did not. Gymnasts and dancers who exercised daily also failed to show an elevated risk (RR = 0.99, 95% CI = 0.54–1.77, not shown on Table 1).

Cigarette Smoking and Alcohol Use. The risks associated with cigarette smoking and alcohol also appear on Table 1. Both risk factors show evidence of a dose-response relationship with twofold increases in secondary amenorrhea at the higher dose (one pack of cigarettes or more per day; alcohol use more than several times per week). Cigarette smoking and alcohol use in this sample were related: girls who smoked were twice as likely to drink, and girls who drank were twice as likely to smoke. Both variables were related to age, with older girls more likely to both smoke and drink. Neither variable was related to social class. In contrast to adults, smoking here was not related to BMI: smokers in this adolescent sample were *not* of lighter relative weight than nonsmokers.

Risk Factors for Secondary Amenorrhea: Multivariate Analysis. Table 2 presents the final model from successive logistic regression and cross-classification analyses.[55–56] It reports the probability of exposure (percent of girls with the characteristic), the RRa, the excess fraction for the population, and the attributable risk in those exposed to a risk factor.[50]

Of particular importance to clinicians is binge-purge behavior. As Figure 1 shows, the risk associated with binge-eating behavior was modified by the level of purging (laxative use or self-induced vomiting). The statistical interaction suggested by Figure 1 was significant ($P < .001$). Because laxative use in combination with binge-eating rarely occurred in the absence of self-induced vomiting (n = 69), laxative use was combined with self-induced vomiting for the purposes of these analyses. Binge eating was a risk factor for secondary amenorrhea only when it occurred in combination with purging (and vice versa). Given the striking pattern of results in Figure 1, binge-purge behavior was modeled with two variables: partial binge-purge behavior, defined as self-induced vomiting or laxative use in conjunction with a single *DSM-III* binge-eating behavior (RRa = 1.99, 95% CI = 1.39–2.81), and complete binge-purge behavior, defined as self-induced vomiting or laxative use in conjunction with two or three *DSM-III* binge-eating behaviors (RRa = 4.17, 95% CI = 2.54–6.52) (Table 2).

Girls who smoked a pack of cigarettes or more per day were at excess risk for secondary amenorrhea, even with statistical control for other variables in the model. The variable representing lower levels of exposure to cigarettes (less than a pack per day) was not statistically significant in the final multivariate model, but the point estimate of the effect (RRa = 1.35, 95% CI = 0.90–1.72) (Table 2) was intermediate, consistent with a dose-response relationship. To the extent that there were age differences in the association between smoking and secondary amenorrhea, there was a nonsignificant tendency for the association to be stronger in older girls. Unfortunately, no information was available as to how long the girls had been smoking.

A number of variables contributed little to the model after adjustment for other associated variables. To the extent that diet pills, diuretics, or simple duration of dieting or fasting was associated with increased rates of amenorrhea, it appeared to be due to the association of these variables with other risk factors (i.e., weight fluctuation and binge-purge behavior).

The decision to drop alcohol from the final model was made only after examining the effects of alcohol consumption across levels of other risk factors. No excess risk was apparent above and beyond the effects of confounding variables.

Focusing on the population excess fractions in the fourth column of Table 2, it is apparent that many of the cases of secondary amenorrhea in the population were associated with behavior: 12% with smoking and 21% with binge-purge behavior. The direction of effect was less compelling with respect to the fraction associated with weight gain, loss, and fluctuation. However, most weight fluctuation in the population coincided with some form of weight control behavior (85%). The final column of Table 2 provides adjusted estimates of attributable risk in girls actually exposed to the model risk factors.

It was not possible to confirm the results of the model presented in Table 2 with a complete cross-classification of risk factors because the number of possible combinations is unwieldy (8640, if BMI is categorized). As an alternative, the data of primary interest are presented in Figure 2, cross-classifying and collapsing dose categories across smoking, binge-purge behavior, and type of weight change.

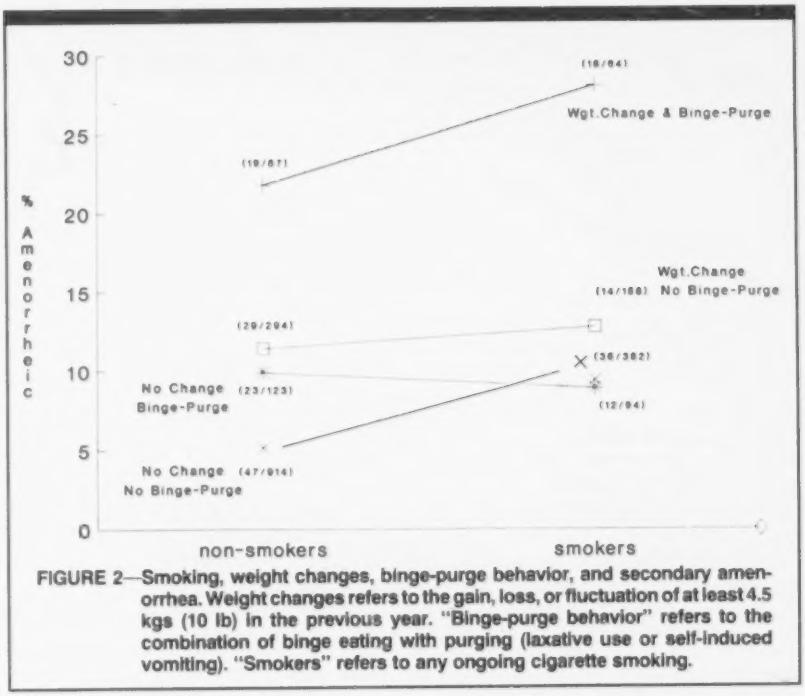

FIGURE 2—Smoking, weight changes, binge-purge behavior, and secondary amenorrhea. Weight changes refers to the gain, loss, or fluctuation of at least 4.5 kgs (10 lb) in the previous year. "Binge-purge behavior" refers to the combination of binge eating with purging (laxative use or self-induced vomiting). "Smokers" refers to any ongoing cigarette smoking.

Discussion

The prevalence of secondary amenorrhea in an unselected adolescent population has not been previously reported. The most methodologically satisfactory study of secondary amenorrhea among adult women (excluding instances attributable to pregnancy and surgical treatment) found a 1-year prevalence of 4.4% for women aged 18 to 45, with a 6.3% prevalence in the age group 18 to 24[57]—somewhat lower than the rate of 8.5% found in this study. Lower rates among adult women may be due to a number of factors, such as maturation of the reproductive cycle[47] or lower rates of the types of behavior examined here.

Certainly, secondary amenorrhea may be due to other underlying medical causes, which must be systematically excluded in a thorough diagnostic workup of each case.[6,7,58] However, such unmeasured risk factors would have to be strongly associated with the risk factors identified by this observational study to render these results spurious. We find an explanation pointing to spurious associations unlikely, given the biologic plausibility of the risk factors nominated.

Binge-eating behaviors were associated with a markedly increased risk for secondary amenorrhea. An association between binge-purge behavior and amenorrhea and/or menstrual irregularity among high school girls was noted by Johnson et al.,[59] but rates and risks for amenorrhea were not fully explored. With respect to the risk for secondary amenorrhea associated with binge-purge behavior, it is likely that purging (self-induced vomiting or laxative use) rather than binge eating is the causal agent. Little, if any, increased risk was evident in the large number of girls who binged but did not purge. The fact that the combination of binge eating and purging carries increased risk is likely to indicate the (unmeasured) increased frequency of purging accompanying the full binge-purge behavioral syndrome.

The mechanism by which binge-purge behavior may affect the hypothalamic-pituitary-ovarian axis is not clear. At least three separate studies[60–62] find evidence in adult bulimic patients of disturbed hypothalamic-pituitary function that is not attributable to emaciation. Possible etiologic factors include nutritional deficiencies,[63,64] insufficient body fat content,[65] intermittent dieting,[66] stress,[60,67,68] exercise,[21] and adaptation to semistarvation at a weight that is considered "normal" by population standards but is below the physiological setpoint for the individual.[62]

Weight changes resulting from weight control practices were associated with secondary amenorrhea above and beyond the specific methods used (Table 2). In particular, weight fluctuation over the past year was associated with the greatest risk for secondary amenorrhea.

This epidemiologic study confirms the importance of weight control in the pathogenesis of amenorrhea in "normal weight" women, a phenomenon long noted in gynecologic case reports[69,70] and recently cited as an underrecognized contributor to infertility.[71] The episodic loss and regain of weight that is so common among adolescent girls[23] may be far from benign.

In these data, the excess risk associated with weight fluctuation in conjunction with binge-purge behaviors may be a proxy for the most severe forms of binge purging or for extremely rapid weight loss. We have controlled statistically for significant weight loss (4.5 kg) in the past year,

but these data did not allow us to take into consideration how rapidly these weight changes occurred.

Several clinical studies have also found a relationship between weight fluctuation and amenorrhea. Copeland and Herzog[16] found that, among normal weight bulimic patients without a history of anorexia nervosa, those who had gained weight from a previously lower weight had a much higher occurrence of amenorrhea than those who had not. Kreipe et al.[72] found a similar association between weight fluctuation and menstrual irregularity in women with subclinical eating disorders. They suggested two possible explanations: (1) these women have a natural weight setpoint that is higher than the weight considered normal on standardized tables; and (2) these women embark on unrealistic "crash" diets in which rapid weight loss (which is only to be regained) disrupts the menstrual cycle. A third possibility, proposed by Devlin et al.,[62] is that weight fluctuation per se may influence hypothalamic-pituitary-ovarian axis functioning.

The risk associated with a simple gain of 4.5 kg or more may reflect weight "rebound" in girls who attempted weight control. This possibility is suggested by the observation that a gain of 4.5 kg was more than would be expected from normal growth tables for girls aged 13 to 18. In addition, girls who had gained weight but had not engaged in any weight control behaviors were at a low risk for secondary amenorrhea (5/103 = 4.9%). A simple weight loss of 4.5 kg or more in the absence of regain or binge-purge behavior was not a strong risk factor for secondary amenorrhea, except among girls at very low relative body weight.

In this adolescent population, cigarette smoking was associated with secondary amenorrhea. Previous studies in adults have found cigarette smoking to be associated with higher rates of physician-attended menstrual disorders,[73] infertility,[74] low birth weight in offspring,[75] spontaneous abortion,[76] and early menopause.[77,78] Several biologic mechanisms have been proposed, such as actions on the hypothalamic-pituitary-ovarian axis, a direct toxic effect on the ovary, and alteration of peripheral estrogen.[79]

The results reported here suggest that as much as 50% of cases of secondary amenorrhea among adolescent girls may be related to behaviors that could be modified. Measures of attributable risk should not be interpreted as implying causality in the absence of other evidence for causality.[50] Nonetheless, these estimates, if cautiously interpreted, can identify the risk groups within a population. Adjusted estimates are also informative even if simple additivity of individual estimates is fallacious. We have interpreted these associations as risks from cross-sectional data on the basis of consistency with clinical studies and biologic plausibility.

Finally, a number of caveats are in order. First, it must be emphasized that underlying medical conditions could have been responsible for both weight fluctuations and the comorbid amenorrhea. A medical workup may thus be warranted, depending on the age of the adolescent and other factors.[6,7] At the population level, however, 85% of the adolescent girls who report weight changes greater than 4.5 kg also engage in some form of weight control, suggesting that the workup should include a careful review of weight control practices as well as smoking.

Second, the failure to find an association between exercise and amenorrhea could be a question of exposure level. Although we examined the risk of secondary amenorrhea in the most extreme exercisers in this population, it is likely that they are not comparable to the career dancers and athletes who have often been the focus of other reports.[18,19,22] However, Wilson et al.[80] also found no relation between exercise levels and menstrual characteristics in healthy adolescent girls. In addition, a number of reports have suggested that a significant amount of amenorrhea in athletes is related to binging and purging.[19,81]

Third, in contrast to clinical studies of menstrual disturbance in women with alcoholism,[17] these data did not implicate alcohol as a risk factor after adjustment for confounding variables (e.g., smoking). There are at least two alternative explanations for this lack of association in these data: (1) the exposure to alcohol was not severe enough or long enough to induce secondary amenorrhea in this young population, or (2) purging and smoking were measured more accurately than alcohol consumption in this study. Because either scenario would produce no association, alcohol cannot be exonerated as a risk factor for amenorrhea.

Fourth, these data are from self-report questionnaires, which doubtless have limitations. However, other investigators have validated adolescent self-reports of menstruation.[36] Our own clinical follow-up of 245 of these girls[39] suggests excellent agreement between the questionnaire data and the clinical interview with respect to both amenorrhea and high-risk eating behaviors. Furthermore, any misreporting of the presence of either secondary amenorrhea or high-risk behaviors would most likely bias against finding associations.

In summary, girls who engaged in binge-purge behavior were at risk for secondary amenorrhea. Second, weight changes, especially weight fluctuation, also appeared to disrupt menstruation. Finally, cigarette smoking was associated with secondary amenorrhea. These data suggest that evaluation of the adolescent with secondary amenorrhea, in both clinical and research settings, should include a careful history to assess these potentially modifiable contributory factors. □

Acknowledgments

This research was supported in part by National Institute of Mental Health (NIMH) grant 1–RO3–MH40527–01 ("Eating Disorders in Adolescents: An Epidemiologic Study") and Biomedical Research Support Grant (New York State Psychiatric Institute); NIMH grant ST32 MH 16434 and NIMH Clinical Research Center grant 30906–07. We thank David Shaffer FRCP (Lond), FRC Psych (Lond), Mark Davies, MPH, and Helen Myers for their invaluable earlier contributions to the study presented here; and Bruce Link, PhD, Diane E. McLean, PhD, Richard Neugebauer, PhD, Steve Ng, MD, Mervyn Susser, MB, BCh, FRCP(E), DPH, and B. Timothy Walsh, MD, for their helpful suggestions with the manuscript.

Hospital Stays Continue 10-Year Decline

Length of stay continues to decline, reflecting a 10-year trend in shortened hospital stays, according to data in the *1990 Length of Stay By Diagnosis and Operation* series released by Healthcare Knowledge Resources in Ann Arbor, Mich.

Hospital stays show a 17% decline since 1981 when the average length of stay in the United States was 6.7 days. From 1989 to 1990 alone, the national average stay for patients in short-term, general hospitals dropped 1.8%, from 5.6 days to 5.5.

The downward trend in length of hospital stay is even more evident when individual diagnoses and procedures are evaluated. For example, the average length of stay for a normal delivery declined almost 37%, from 3.0 days in 1981 to 1.9 days in 1990. Predelivery education, the advent of LDRs (labor-delivery rooms) and pressure from third-party payers contributed to the shortened stay. Experts predict that the decrease in average length of stay for normal deliveries will stop before reaching 1 day.

Regional differences are also a factor in the average length of stay. Traditionally, hospital stays are highest in the Northeast and North Central regions and lowest in the South and West. This pattern was consistent until 1990, when the average length of stay was lower in the North Central region (5.6 days) than in the South (5.7 days). The average length of stay has remained constant in the South since 1987, whereas the North Central region has shown a steady decline. The lowest average length of stay is in the West at 4.8 days; the highest is in the Northeast at 6.2 days.

Healthcare Knowledge Resources' *Length of Stay* data are drawn from the Commission on Professional and Hospital Activities (CPHA) database and reflects over 4 million discharge records from short-term, general hospitals. Data have been collected since 1963 and are available for separate regions, the whole United States, and also for geriatric and pediatric patients.

Predictors of Smoking Prevalence among New York Latino Youth

Linda Dusenbury, PhD, Jon F. Kerner, PhD, Eli Baker, PhD, Gilbert Botvin, PhD, Susan James-Ortiz, MA, and Ann Zauber, PhD

ABSTRACT

Background. We examined prevalence rates and risk factors for smoking among Latino adolescents, using a multiethnic sample of sixth- and seventh-grade students (n = 3129) in 47 New York City public and parochial schools.

Methods. The students completed questionnaires; self-reported smoking data were collected by means of the "bogus pipeline" technique. The largest group of Latino students (43%) was Puerto Rican; 20% were of Dominican background, 7% were Colombian, and 7% were Ecuadorian. "Current smoking" was defined as smoking at least once per month.

Results. A series of logistic regression analyses indicated that peer influence was the strongest predictor of smoking. Family influence was important as well.

Conclusions. The results are discussed in terms of their implications for prevention. (*Am J Public Health.* 1992;82:55–58)

Introduction

Despite a decline in the prevalence of smoking among adult White males since the Second World War, there has been a steady increase in smoking among adult White females and adult minority group members, and the same patterns have been observed among adolescents.[1] According to the US Office of Minority Health,[2] there are important but poorly understood differences in health behaviors within and among various racial and ethnic groups, and this appears to be particularly true for Latinos.[3] Marcus and Crane[4] conclude that Latino men are as likely to smoke as non-Latino men, and that the rates of smoking-related morbidity and mortality among Latino men are expected to rise in the 1990s. Similarly, Escobedo and Remington[5] report that the rate of smoking among Latino women is increasing.

Determining smoking prevalence among Latino groups has been a problem because different studies have used different samples to estimate prevalence, as well as different operational definitions of "smoking." The only data for Latino adolescents come from the Hispanic Health and Nutrition Examination Survey,[6] which used "current smoking" to explore prevalence. That survey found that approximately 1% of Mexican-American adolescents aged 12 to 14 years smoked, compared with 3.5% for Puerto Ricans. In both groups the rate of smoking was three times higher for girls than for boys.

Austin and Gilbert[7] note in a review article that the correlates of substance use (not including smoking) generally are similar for Latino and non-Latino populations, and include lower socioeconomic status, family instability, peer influence, and family influence. However, little information has been available concerning Puerto Rican youth specifically, and no information has been available concerning Dominicans, Colombians, or Ecuadorians.

In the present study, we examined correlates of adolescent smoking among New York City Latino populations attending public and Catholic schools. Previously reported predictors of smoking in White non-Latino populations were tested with the overall sample of Latino youth available in this study.

Methods

This study was part of an ongoing longitudinal investigation of smoking prevention interventions in New York City schools whose student bodies were more than 25% Latino. The intervention was implemented in the sixth and seventh grades. All sixth- and seventh-graders in English-speaking, mainstream classes in the schools participated in the study. A passive consent procedure was used, and more than 90% of the students completed the baseline survey of smoking behavior. Data for the present study were derived from the baseline survey and were collected prior to the intervention; the sample

TABLE 1—Current Smoking[a] Prevalence among Latino Students, by Gender and Age

Age	Females n	Females %	Females 95% CI	Males n	Males %	Males 95% CI
Puerto Rican						
≤ 12 years	245	5.3	2.5–8.1	251	1.6	0–3.1
13 years	371	8.1	4.9–11.4	253	5.1	2.4–7.9
≥ 14 years	113	20.4	12.9–27.8	145	13.1	7.6–18.6
Other Latino						
≤ 12 years	465	4.1	2.3–5.9	371	1.3	0.2–2.5
13 years	331	3.6	1.6–5.6	309	4.9	2.5–7.3
≥ 14 years	99	6.1	1.3–10.8	127	7.1	2.6–11.6

Note. CI = confidence interval.
[a]"Current smoking" was defined as smoking at least once per month.

consisted of students from both experimental and control schools.

The schools eligible for inclusion in this study were Catholic and public schools in New York City whose student bodies were at least 25% Latino. Forty-seven schools in New York City participated in the intervention study; 36 were Catholic schools and 11 were public schools. The sample was evenly distributed between the two school types, with 2681 students (49%) from Catholic schools and 2820 students (51%) from public schools. Both public and Catholic schools in New York City serve lower-income, urban minority youth.

Subjects

A total of 3129 sixth- and seventh-grade students who identified themselves as Latino or Hispanic on the questionnaire participated in the study. The mean age of the students was 12.61 years (range, from 10 to 18 years). Forty-eight percent of the students were male. Of the total sample, 43% were Puerto Rican, 20% were Dominican, 7% were Colombian, and 7% were Ecuadorian. The remaining 23% of the students identified with another Latino subgroup or with more than one Latino subgroup.

Instrument

The instrument was a questionnaire consisting of 143 items concerning demographics, substance use, and psychosocial factors. It included items on self-reported smoking and the perceived social support for smoking.

Background variables. Twelve items were used to elicit basic background information concerning gender, age, family structure, and academic performance (grades). In addition, students' race was determined by a single item. If students indicated that they were Latino or Hispanic, they were asked to indicate their Latino subgroup status, which included Puerto Rican, Dominican, Colombian, Ecuadorian, and other Latino subgroups and subgroup combinations. Only those students identifying themselves as Latino or Hispanic were included in the present study.

Smoking status. A dichotomous (yes or no) item was used to assess smoking during the last month. A general 11-point scale was used to assess smoking frequency. Data from this 11-point scale were used to group students into three categories: those who had never smoked, those who smoked less than monthly (experimental smokers), and those who smoked monthly to daily (current smokers).

Perceived social influences on smoking. Social influences on smoking were assessed, including (1) smoking by significant others (friends, siblings, and parents), (2) perceived attitudes of parents and friends toward respondents' smoking, and (3) perceived prevalence of general smoking rates among peers and adults (normative expectations). Smoking by friends was measured on a 5-point scale ranging from "none" to "almost all." Smoking by older siblings was measured on a 4-point scale ranging from "none" to "three or more." Smoking by parents was assessed in separate items for the respondent's father and mother ("Does your father [mother] smoke cigarettes?"; responses included "have no father/mother," "no," "used to but quit," and "yes"). The perceived attitudes of parents and friends toward the respondent's smoking were assessed, in separate items, on a 5-point scale ranging from "strongly against it" to "strongly in favor of it." The perceived prevalence of general smoking rates among peers and adults was measured, in two items ("In your opinion, how many people your age [adults] smoke cigarettes?"), on a 6-point scale ranging from "none" to "almost all."

Procedure

The survey was administered by project staff members. The students completed the questionnaire during a regular 40-minute classroom period. Teachers were not involved in the data collection activities and the students were assured that their answers would remain confidential. The students also provided a breath sample for carbon monoxide testing. Although correlations between carbon monoxide levels and self-reports of smoking behavior among students in this age group are typically too low to use as an independent validity check, this "bogus pipeline" procedure has been found to increase the veracity of self-reported smoking data.[9]

Data Analysis

The data were analyzed with SAS software.[10] First, within the major ethnic groups, males and females were compared in terms of smoking prevalence. Next, logistic regressions were used to analyze predictors of smoking status. No significant differences were found between school types; therefore, the two groups were combined.

Results

Table 1 presents the prevalence of current (at least monthly) smoking by ethnic and gender groups. Older students were generally more likely than younger students to be current smokers. In addition, Puerto Rican female students of all ages tended to have higher current smoking prevalence rates than Puerto Rican male students or other female students.

Two logistic regression analyses were carried out to compare adolescents who had never smoked (n = 2180) with adolescents who had smoked at least once (experimental smokers, n = 616), and adolescents who were current smokers (n = 99) with all others (n = 2697). Demographic and prosmoking social-influence variables were entered into the equations simultaneously. Individuals for whom any of the variables in the equation was missing were omitted from the analysis. Latino groups were compared using Puerto Ricans as the reference group. Prosmoking social-influence variables included prevalence of smoking among friends, siblings, and parents; perceived smoking prevalence among youth and

adults generally; and parents' and friends' attitudes about respondents' smoking.

Several demographic variables emerged as significant predictors of experimental smoking (Table 2). Specifically, older students and students with lower academic performance were more likely to have ever smoked.

Latino students who were Dominican, Colombian or Ecuadorian (South American), or from another Latino category were somewhat more likely to have ever smoked than were Puerto Rican students. Thus, even though Puerto Rican girls were more likely to be current smokers (see Table 1), Dominicans, Ecuadorians, and Colombians were more likely to have ever smoked by seventh grade.

Prosmoking social influences were also related to experimental smoking. The general prevalence of smoking among peers was a significant predictor of having smoked: the odds of having smoked were 55% lower for students who reported that few to none of their peers smoked than for students who reported that from more than half to all of their peers smoked.

The major predictor of experimental smoking was the proportion of friends who smoked. Students who reported that from 50% to 100% of their friends smoked were eight times more likely to have ever smoked than were students who reported having no friends who smoked. Number of siblings who smoked and maternal smoking were also predictors. Parents' and friends' attitudes toward respondents' smoking were predictors: less negative attitudes were correlated with greater odds of smoking.

Table 3 presents the significant predictors of current smoking. Although the number of students who met the criterion for current smoking was small (n = 99), the results of this exploratory analysis were largely consistent with the findings of the previous logistic regression analysis. Specifically, age and academic performance were significant predictors of current smoking. In addition, the proportion of friends who smoked was the most important predictor of current smoking, as it was for experimental smoking. Students who reported that between 50% and 100% of their friends smoked were 17 times as likely to be current smokers. Sibling and maternal smoking also increased the odds of current smoking, as they had in the case of experimental smoking, but in the case of current smoking, paternal smoking also emerged as a significant predictor. Parental attitudes again were correlated with current smoking, although friends' attitudes did not emerge as a significant predictor.

Discussion

This study examined prevalence rates and risk factors for smoking among Latino adolescents, using a multiethnic sample of sixth- and seventh-grade students in New York City. The pattern of smoking among the different Latino subgroups in this study is fairly straightforward, and is consistent with patterns found in previous studies of non-Latino populations. Our findings suggest that age, academic performance, Latino subgroup, and social influences, including friends who smoke as well as family members who smoke, are all related to smoking status. Consistent with Austin and Gilbert's[7] review of predictors of Latino substance use (not including smoking), peer influences were the strongest predictors of smoking for Latinos in the present study.

Several factors may limit the generalizability of the present study. The first concerns the sample. Students may differ from dropouts or nonstudents. Furthermore, the students who participated in this study were those who were enrolled in English-speaking classes. Therefore, this study does not provide information concerning the population of Latino students enrolled in bilingual classes.

The results of this study have several implications for prevention. Predictors of smoking in this Latino sample are also consistent with findings for White non-Latino adolescents[11] and Black non-Latino adolescents.[12] The results suggest that in interventions with sixth- and seventh-graders *in school settings,* the differences between ethnic groups may not be as important as the overall similarities with respect to predictors of smoking. Furthermore, the interventions most likely to prevent smoking would be those that promote peer resistance skills, and the motivation to use those skills, in all groups. This does not mean that cultural differences are not important; the potential reception by the target audience might be enhanced, and the efficacy of

the intervention maximized, by material sensitive to a whole range of cultural orientations. Further study is needed to explore this issue. The results of this study also suggest that smoking prevention in schools with large Latino populations might be enhanced by programs that also address family influences on student smoking.

This study extends previous knowledge of the prevalence and concurrent predictors of smoking among Latino youth. Additional research will be necessary to develop a complete model for understanding the etiology of smoking in these groups. For example, the relationship of language and acculturation to smoking is complex and requires a comprehensive examination. Other cultural factors that may play a role in the etiology of smoking in Latino youth and require additional research include community influences, microcultures, and cultural beliefs and attitudes concerning health.[13] Finally, individual psychosocial factors, such as knowledge and attitudes, were not included in this study, but these may also emerge as powerful predictors of smoking in Latino youth. □

Variations in Asthma Hospitalizations and Deaths in New York City

Willine Carr, DrPH, Lisa Zeitel, MPH, and Kevin Weiss, MD

ABSTRACT

Background. Recent reports have identified New York City as having asthma mortality rates that are substantially higher than expected based on US rates. This study investigates the problems of asthma morbidity and mortality in New York City.

Methods. Data on asthma hospitalizations (1982 to 1986) and deaths (1982 to 1987) among persons aged 0 to 34 years were studied. Descriptive and multivariate techniques were used to examine differences in rates among subgroups and across geographic areas.

Results. The average annual hospitalization rate was 39.2 per 10 000; the mortality rate was 1.2 per 100 000. Hospitalization and death rates among Blacks and Hispanics were 3 to 5.5 times those of Whites. Large geographic variations in hospitalizations and mortality occurred. Asthma hospitalization and mortality rates were highly correlated ($r = .67$), with the highest rates concentrated in the city's poorest neighborhoods. Household income, percentage of population Black, and percentage of population Hispanic were significant predictors of area hospitalization rates (adjusted $R^2 = .75$).

Conclusion. These findings provide a basis for focusing investigations of the causes of variations in asthma outcomes and targeting interventions to reduce the disproportionate morbidity and mortality borne by poor and minority populations. (*Am J Public Health.* 1992;82:59–65)

Introduction

Between 9 and 12 million persons in the United States have asthma, a chronic disease that is a major cause of disability for many persons and a cause of death for some.[1] Asthma is often associated with long-term psychological and financial burdens and is a leading reason for the utilization of health services.[2]

Although the past 20 years have witnessed major advances in the treatment and control of asthma, hospitalizations for asthma are frequent and have increased substantially; asthma mortality has also increased. Evans and colleagues found that between 1965 and 1983, hospitalizations of adults for asthma increased nationally by approximately 50%.[1] Gergen and Weiss reported that asthma hospitalizations of children increased by 47% from 1979 to 1987.[3] From 1980 to 1987, U.S. asthma mortality rates among all ages increased by 31%.[4]

Recent evidence suggests that these increasing trends in asthma hospitalizations and mortality are not occurring evenly across the United States.[5] The trends are to some extent driven by the rates in a few large cities. Significant among these is New York City, where, with less than 3% of the nation's population, approximately 6% of all asthma hospitalizations and 7% of all asthma deaths occurred in 1986. From 1982 to 1985, the number of asthma deaths in New York City among persons aged 5 to 34 was more than three times the number that would be expected based on national rates.[6] Other studies have shown large geographic disparities in asthma hospitalization rates among counties,[7] cities,[8] and hospital market areas.[9] This study is the first to characterize variations in both asthma hospitalizations and asthma deaths among racial/ethnic subgroups and across geographic areas in a single city, and to examine the extent to which area-level sociodemographic factors account for geographic differences.

Methods

Study Population

Asthma hospitalizations and deaths among New York City residents aged 0 through 34 were studied. Hospitalizations were examined for persons with a principal diagnosis of asthma (ICD-9 CM codes 493–493.91) who were discharged from nonfederal general care hospitals in the city during the years 1982 through 1986. Deaths were studied for persons with asthma (493–493.91) listed as the underlying cause of death during the years 1982 through 1987. The additional year for mortality data was included to increase the number of events.

Data Sources

Computerized data on all hospital discharges (asthma and nonasthma) were obtained from the New York State Department of Health. Each discharge record included the patient's age, race/ethnicity, zip code of residence, type of admission, diagnoses and procedures,

TABLE 1—Hospitalizations for Asthma among New York City Residents Aged 0–34 Years (1982 to 1986)

	Number of Hospitalizations	Average Annual Rate[a]	95% Confidence Interval	Percent Change in Rate 1982–1986
All New York City residents aged 0–34	74 292	39.2	38.7–41.7	17.4
Age				
Under 5 years	23 855	101.5	93.6–109.3	24.4
5–9 years	12 348	55.3	51.7–58.8	8.9
10–19 years	16 856	31.5	30.9–32.1	1.0
20–34 years	21 233	23.5	20.7–26.4	29.0
Sex				
Male	37 629	40.6	37.7–43.6	21.8
Female	36 663	37.8	35.6–40.0	13.0
Race/Ethnicity				
White, non-Hispanic	9 887	12.2	11.7–12.7	5.1
Black, non-Hispanic	31 101	59.9	55.3–64.5	21.1
Hispanic	29 633	62.9	59.1–66.6	8.0

Note. Data for racial/ethnic groups do not add to total because persons categorized as "other" are not shown in the racial/ethnic details.
[a]Per 10 000 population.

length of hospital stay, and expected payment source. The data represent hospitalization events and not individual persons. It was not possible to identify multiple admissions of the same patient.

Mortality information came from vital certificates data compiled by the New York City Department of Health and included the decedent's age, race/ethnicity, and zip code of residence.

Information on population characteristics came from the 1980 U.S. Census. Rates were calculated using the U.S. Census STF-3B data file. Sociodemographic measures used in the multivariate analyses were obtained from a census file prepared by the Claritas Corporation.[10]

Data Analysis

Using descriptive and multivariate techniques, this study focused on variations in asthma hospitalizations and deaths among subgroups and across geographic areas of New York City.

Subgroup analysis. Data were examined for both sexes, for four age groups under age 35, and for racial/ethnic groups categorized as (1) White, non-Hispanic; (2) Black, non-Hispanic; (3) Hispanic; and (4) other.

Rates of hospitalization and mortality were studied at the citywide level for each sex, age, and racial/ethnic group. Since hospitalization rates were essentially unaltered by age and sex adjustment, unadjusted rates are presented. Ninety-five percent confidence intervals for hospitalization and mortality rates were calculated.[11,12] Chi-square tests were used to test the significance of the differences in changes in hospitalization rates among racial/ethnic groups over time.[11] The significance of differences in length of stay among discharges with different payers was tested using analysis of variance.[13]

Small-area analysis. Hospitalizations and deaths were also studied for populations residing in different geographic areas, including the city's 5 boroughs or counties, its 41 neighborhoods, and its 165 residential zip code areas. The populations of persons aged 0 to 34 ranged from 10 090 to 259 515 in the neighborhoods and from 1629 to 67 411 in the zip code areas. Unadjusted rates of hospitalization and death, with ninety-five percent confidence intervals (CIs), were calculated for each geographic area. (Age and sex adjustments altered the rates very little.) At the neighborhood level, the Pearson's product moment correlation coefficient was used to establish the association between neighborhood-level asthma hospitalization and death rates and the association between these outcomes and the income and racial/ethnic compositions of neighborhoods.

Multiple linear regression models were developed, using the SPSS PC Plus Regression procedure, to define the extent to which poverty and race/ethnicity explained geographic variations in hospitalization rates.[14] Zip code areas (N = 165) were used to maximize statistical power and the homogeneity of populations within the geographic areas. The dependent variables were hospitalization rates for persons aged 0 to 34 and for four age-specific groups.

The independent variables used in the regression models were zip code–level measures of socioeconomic status, including median household income, percentage of the population that is Black, and percentage of the population that is Hispanic. Different models were developed by specifying the order in which the explanatory variables were entered. The model shown was selected because it achieved the highest predictive power. Transformations were applied to normalize independent and dependent variables that had skewed distributions; the transformation selected in each case was the one that minimized skewness. Although each pair of predictors was significantly correlated the relationships among the three predictors were not sufficiently high to create a multicollinearity problem in the regression analysis. Residuals in each model were randomly distributed, and thus were not correlated with any of the independent variables.

Results

Asthma Hospitalizations

From 1982 through 1986, New York City residents below age 35 had an average of 14 856 asthma hospitalizations per year and an average annual hospitalization rate of 39.2 per 10 000 population (Table 1). The highest hospitalization rate, 101.5 per 10 000 population, occurred among children under 5 years of age; rates declined to a low of 23.5 per 10 000 for persons aged 20 to 34. Nearly 90% of asthma hospitalizations were unscheduled, primarily resulting from admissions through hospital emergency rooms. Only 0.1% of asthma hospitalizations ended in death.

Blacks and Hispanics accounted for 81.8% of all asthma hospitalizations. The average annual rate per 10 000 population was 12.2 among Whites, 59.9 among Blacks, and 62.9 among Hispanics; Blacks and Hispanics, therefore, had rates five times as high as those of Whites. For each of the age-specific cohorts, minorities were found to have rates at least three times as high as those of Whites.

Asthma hospitalizations increased from 35.8 per 10 000 population in 1982 to 43.1 per 10 000 in 1986, a growth of 17.4% (Table 1). This increase occurred at a time when total hospitalizations for persons under age 35 were declining. In 1982, hospitalizations for asthma constituted 4.4% of all hospitalizations of persons under 35; by 1986, asthma hospitalizations constituted

6.3% of all hospitalizations in this age group. (Total hospitalizations exclude routine obstetric and newborn hospitalizations.) The largest increases in asthma hospitalization rates occurred among persons under age 5 (24.4%) and among persons aged 20 through 34 (29.0%). The increase in the rate among males was 1.7 times the increase for females. All three racial/ethnic groups experienced increases; however, the increase was significantly larger for Blacks than for Hispanics ($\chi^2 = 19.3$, $df = 1$) and Whites ($\chi^2 = 15.2$, $df = 1$). One of the largest race-specific increases (46.4%) occurred among White children under age 5, although the absolute value of this rate in 1986 was still substantially below that of Black and Hispanic children (Figure 1). Black individuals aged 20 to 34 also experienced a very large increase (49.3%) in this rate.

Asthma accounted for substantial use of hospital and third-party-payer resources. Asthma hospitalizations of persons under age 35 amounted to 302 734 days of patient care, 4.1 days per discharge. Length of stay was significantly longer for hospitalizations with Medicaid as the expected source of payment than for hospitalizations with other expected sources of payment ($F = 50.4$, $df = 1$, $p = .0001$). Medicaid was the expected source of reimbursement for 63% of asthma patient days of care, versus 51% of all patient days. (Total patient days exclude routine obstetric and newborn days.)

Asthma Mortality

From 1982 to 1987, a total of 271 deaths due to asthma occurred among New York City residents aged 0 to 34; this represents an average annual rate of 1.2 deaths per 100 000 population (Table 2). About 30% of all asthma deaths occurred among hospitalized asthma patients.

The majority of asthma deaths (68.3%) were among persons aged 20 to 34. As with asthma hospitalizations, more than three fourths (76.2%) of asthma deaths occurred among Blacks and Hispanics. Deaths among Blacks occurred at an average annual rate of 2.2 per 100 000 population, which was 5.5 times the asthma death rate among Whites; the asthma mortality rate among Hispanics, 1.3 per 100 000, was 3 times the White rate.

Asthma mortality peaked at 63 deaths in 1985 (1.7 per 100 000 population, CI = 1.3–2.1), up from 35 in 1982 (0.9 per 100 000, CI = 0.7–1.3). After 1985, mortality rates declined overall and for each of the four age and three racial/ethnic groups.

Black, non-Hispanic	135	2.2	1.8–2.6
Hispanic	73	1.3	1.0–1.6

Note. Data for racial/ethnic groups do not add to total because persons categorized as "other" are not shown in the racial/ethnic details.
[a]Per 100 000 population.

Geographic Variations

Neither asthma hospitalizations nor deaths were distributed evenly across the city. Among New York's five boroughs, average annual asthma hospitalization rates ranged from 65.8 per 10 000 population in the Bronx—1.7 times the citywide rate—to 21.3 per 10 000 in Queens—about

one half the citywide rate (Table 3). The average annual asthma mortality rates were higher in the Bronx (1.7 per 100 000 population) and in Brooklyn (1.4 per 100 000) than in other boroughs.

Differences in asthma hospitalization rates among the city's neighborhoods are striking (Figure 2). The average annual hospitalization rate in the neighborhood with the highest rate was nearly 16 times the rate in the neighborhood with the lowest rate. The highest rate, 115.0 per 10 000 population (CI = 105.7–124.4), occurred in East Harlem in Manhattan, where 93% of the population is Black or Hispanic and where the 1979 median household income was under $11 000. The lowest rate, 7.2 per 10 000 (CI = 5.8–8.7), occurred in Greenwich Village–Soho in Manhattan, a neighborhood that is 70% white with a 1979 median household income that exceeded $19 000. Neighborhood asthma hospitalization rates showed a high negative correlation with neighborhood median household income ($r = -.80$), and were positively correlated with percentage of the population Black ($r = .74$) and Hispanic ($r = .75$).

Asthma death rates also varied greatly across areas (Figure 3). Neighborhood asthma death rates, like hospitalizations, were negatively correlated with median household income ($r = -.65$), and positively correlated with percentage of population Black ($r = .56$) and percentage Hispanic ($r = .59$). The highest asthma mortality rate also occurred in East Harlem, where the average annual death rate was 4.9 per 100 000 population (CI = 3.0–7.9), more than four times the citywide rate. Of the asthma deaths for which the neighborhood of the deceased could be identified (N = 252), 45% occurred in only 6 of the city's 41 neighborhoods, neighborhoods that accounted for only 21% of the city's population. The 1979 median household income in these neighborhoods was under $13 000.

Variations in asthma hospitalizations and deaths follow virtually the same geographic pattern. High rates of both asthma hospitalization and asthma death are strongly associated with both race/ethnicity and poverty. Not surprisingly, then, asthma hospitalization rates by neighborhood are highly correlated with asthma mortality rates ($r = .67$).

Multiple Regression Analysis

Three independent variables were examined for their contribution to asthma hospitalization rates. (See Table 4 for correlation matrix.) Among persons aged 0 to

TABLE 5—Results of Regression Analyses for Asthma Hospitalizations

Age Group	Variable[a]	Change in R^2	Zero Order Correlation Coefficient	Partial Correlation Coefficient	β	*P*
0–34 years (Adjusted R^2 = .75)	Median household income	.57	−.75	−.47	−.39	<.0001

	% Population Hispanic	.01	.61	.19	.14	<.05
0–4 years (Adjusted R^2 = .68)	Median household income	.48	−.69	−.38	−.34	<.0001
	% Population Black	.20	.75	.62	.53	<.0001
	% Population Hispanic	.00	.54	.12	.09	NS[b]
5–17 years (Adjusted R^2 = .63)	Median household income	.49	−.70	−.34	−.33	<.0001
	% Population Black	.12	.67	.48	.39	<.0001
	% Population Hispanic	.03	.62	.28	.24	<.001
18–34 years (Adjusted R^2 = .67)	Median household income	.51	−.71	−.41	−.38	<.0001
	% Population Black	.16	.72	.56	.47	<.0001
	% Population Hispanic	.01	.57	.14	.11	NS[b]

Note. The change in R^2 in column 3 reflects the effect of adding a variable to the model. The remaining statistics and probability values are for the final model when all three variables have been entered.
[a]% Population Black and % Population Hispanic were log transformed.
[b]NS = not significant (>.05).

34, nearly three quarters of the geographic variation in asthma hospitalization rates among zip code areas can be accounted for by two of the three ecologic predictors examined: median household income and percentage of the population that is Black (see Table 5). Median household income is significantly negatively related to an area's asthma hospitalization rate ($\beta = -.39$, $P < .0001$), and the percentage of the population that is Black has a significant positive effect on the hospitalization rate ($\beta = .49$, $P < .0001$). The addition of the Hispanic variable to the model, although significant ($\beta = .14$, $P < .05$), increased the amount of variance accounted for by less than 1%. No significant interaction effect due to income was found when interaction terms were included in the model.

Although median household income and percentage Black are both needed to maximize the model's predictive power, each variable on its own is an important determinant of the asthma hospitalization rate in an area. When either of these variables was included as the sole independent variable, it explained about 57% of the disparity in hospitalization rates.

The age-specific models explain between 63% and 68% of the total variation in asthma hospitalization rates. For asthma hospitalization rates of individuals aged 0 to 4 and 18 to 34, the significant predictors were income and percentage Black. However, for the age group 5 to 17, percentage Hispanic also made a significant contribution to explaining the geographic variation.

Discussion

This study clearly demonstrates that the adverse asthma outcomes hospitalization and death are a large health problem in New York City, particularly for Blacks and Hispanics and for residents of low-income areas. These results are consistent, in part, with findings of previous research. Wennberg et al. identified asthma as a discharge diagnosis with a high degree of variation across hospital market areas

FIGURE 3—Average annual asthma death rates per 100 000 population among New York City residents aged 0–34 years, by neighborhood, 1982–1987.

in Maine.[9] In a Maryland study, Wissow and colleagues found large differences in childhood asthma hospitalizations across the state. Their study demonstrated that the greater risk of hospitalization among Black children could be explained largely by poverty rather than race.[7] Perrin et al. showed marked differences in childhood asthma hospitalizations among three cities—Boston, New Haven, and Rochester—and also hypothesized that these differences were related to differences in socioeconomic status.[8]

The present study explicates the correlates and predictors of two asthma outcomes among children and young adults within a single city. The results demonstrate both the high correlation of asthma hospitalization and mortality rates and the strong association of both of these outcomes with community poverty. Although poverty probably accounts for much of the association between asthma hospitalizations and deaths, other possible reasons for this association need to be examined. In addition, the findings indicate that, at the area level, race/ethnicity plays a definite role in asthma hospitalizations when income level is controlled, suggesting that the higher rates of hospitalization found in minority communities are not entirely a function of community poverty. Similarly, the percentage of the population that is Hispanic is significantly associated with asthma hospitalizations in one age group (5- to 17-year-olds), even when the effects of both income and percentage Black are controlled. This unique significance of race/ethnicity should be taken into account in planning epidemiologic studies and health programs for the control of asthma. The large increase in the hospitalization rate for White children under age 5 requires further investigation, but it may be due, in part, to changes in physician recognition and understanding of asthma in this age group.

The high degree of geographic and subgroup variation in asthma hospitalizations and deaths may be driven by differences in the underlying prevalence or case severity for this disease or by differences in environmental exposures. Evans et al. found that asthma is slightly more common in Black than in White populations, especially in younger age groups.[1] The prevalence of asthma among Hispanics is not well documented, although Hispanic children of Puerto Rican origin may have a higher prevalence than non-Hispanic Whites or Blacks.[15] Researchers have found no or only very slight differences in the prevalence of asthma between those above and those below the poverty level.[1] With respect to case severity, there is no information on trends in asthma severity among segments of the U.S. population or on whether asthma is a more severe disease among minorities and poor persons than among others. Finally, the extent and impact of differential exposures among subgroups and across geographic areas to the indoor and outdoor pollutants associated with asthma morbidity are not well established.[16–18]

Even if significant differences in disease prevalence, case severity, and environmental exposures associated with poverty or race/ethnicity are hypothesized, they are unlikely to account fully for the very large disparities in asthma hospitalizations and deaths observed in this study. Clearly, other potential explanations for these differences must be examined, including the role of the health care system.

Asthma is a highly manageable disease. Yet, it has been suggested that inadequate medical management of asthma is common; management tends to be poorest and morbidity, and possibly mortality, highest among patients with the poorest understanding of the disease and its treatment.[19] Given the reversibility of asthma symptoms and the availability of apparently effective treatment strategies,[20] asthma hospitalization and deaths are potentially avoidable outcomes. An excess of these negative outcomes among minorities and the poor may signal possible problems in the structure and functioning of the health care delivery system.[21]

Differences in the supply of health care resources have been hypothesized to account for geographic variations in health services utilization and health outcomes, although, to date, researchers have not documented this relationship with asthma hospitalizations. Wissow et al., for example, found that variations in childhood asthma discharge rates in Maryland were not associated with the supply of hospital beds or with the ratio of population to primary-care physicians.[7] The effect of supply factors was not examined in the present study. However, given the vast supply and distribution of health care resources in New York City, it is reasonable to hypothesize that rather than resource supply per se, the types, configuration, and organization of providers and services available to different population groups may have an impact on asthma outcomes. For example, German and colleagues found that different types of usual sources of health care were related to whether inner-city children in Baltimore received regular care for asthma.[22] The populations found to be at high risk for asthma hospitalization and death in the present study are heavily dependent on hospital outpatient departments and emergency rooms for their ambulatory care.[23]

Differences in medical practice styles, reflecting the exercise of physicians' discretion in the way illnesses are treated, are also important determinants of geographic variation in hospital utilization for many medical conditions.[9] Whether practice styles significantly influence within-city variations in admissions for asthma is an important question in light of the fact that asthma is the leading reason for hospitalization among the age group studied (excluding routine obstetric and newborn hospitalizations). This question is especially important for cities that have overburdened hospital systems with excessively high occupancy rates (such as New York),[24] and should be of particular concern to Medicaid policymakers, since Medicaid is by far the major payer for asthma inpatient services for the age group studied. The observed correlation of asthma hospitalizations and asthma deaths may indicate, however, that hospitalizations are a reasonable indicator of asthma morbidity, and that differences in rates of hospitalization are not primarily a function of differences in admission practices.

The data used in this study have certain limitations. Errors and inconsistencies in the coding of principal diagnoses and underlying causes of death may exist, although accurate identification of asthma morbidity and mortality is least problematic among the age group studied.[25,26]

Another limitation is that identification and coding of race and ethnicity are subject to error and the coding differs for the two data sets used. The mortality data separately identify race and ethnicity, whereas the hospitalization data do not. This difference may account for some of the ethnic patterns shown, such as the higher hospitalization rate but lower mortality rate of Hispanics than of Blacks. Further, a lack of accurate population counts by race/ethnicity at the zip code level precluded direct examination of racial/ethnic patterns of asthma outcomes within small geographic areas.

The hospitalization data represent episodes of care and are not person-specific. It was not possible to determine whether observed differences in rates among racial/ethnic and geographic sub-

groups were due to higher numbers of individuals being hospitalized or a higher rate of readmission among some subgroups. This problem is being investigated by the authors, using a special data set that links individuals' hospitalizations over time.

Finally, the small-area data cannot be used to infer individual-level relationships because of the risk of ecological fallacies.[27] However, as suggested by Kerner and colleagues and as demonstrated in this study, small-area data have valuable uses in identifying high-risk areas and subgroups toward which interventions should be targeted.[28] The intracity findings reported here provide a basis for more detailed and narrowly focused investigations of the factors that contribute most significantly to determining the outcomes for minorities and residents of low-income areas of a common and—usually—relatively benign disease. Such investigations should lead to the design and targeted implementation of public health policies and comprehensive clinical interventions that can reduce the disproportionate burden of asthma morbidity and mortality borne by minorities and the poor. □

Diversity of Tick Species Biting Humans in an Emerging Area for Lyme Disease

Robert P. Smith, Jr, MD, MPH, Eleanor H. Lacombe, MT(ASCP), Peter W. Rand, MD, and Richard Dearborn

ABSTRACT

Background. Although most tick bites in humans in areas of the northeastern United States in which Lyme disease is highly endemic are due to *Ixodes dammini*, no study documents the frequency of *I. dammini* bites in low-prevalence or emerging areas for Lyme disease. Data on the proportion of tick bites in humans that are due to *I. dammini* in a region may have implications for public health policy and clinical management.

Methods. A statewide survey of the tick species that parasitized humans in Maine was conducted during 1989 and 1990. Tick submissions from throughout the state were elicited through media announcements. All ticks that had been removed from humans were identified, and data were collected that included bite seasonality and geography and demographics of tick bite victims.

Results. Of 709 ticks submitted, only 17% were *I. dammini. Ixodes cookei*, a vector for Powassan encephalitis, accounted for 34% of bites, and *Dermacentor variabilis* accounted for 45%. Other tick species were occasionally implicated.

Conclusions. The likelihood that a tick bite was due to *I. dammini* was lower in Maine than in areas in the northeastern United States in which Lyme disease is highly endemic. Other tick vectors, associated with diseases other than Lyme disease, were more frequently implicated. Regional tick bite surveys may prove useful in assessing the risk of Lyme disease following a tick bite. (*Am J Public Health.* 1992;82:66–69)

Introduction

In areas in which Lyme disease is highly endemic, the northern deer tick, *Ixodes dammini*, accounts for up to three fourths of tick bites in humans.[1,2] As many as 30% to 70% of nonlarval deer ticks in these areas may be infected with *Borrelia burgdorferi*.[3–6] Because unrecognized Lyme disease can have severe consequences, many physicians in high-prevalence areas routinely treat patients with a recent history of a tick bite with oral antibiotics in an attempt to prevent the development of infection. One double-blind placebo-controlled study of this practice failed to demonstrate a clear benefit with treatment, even though all study participants were bitten by *I. dammini* and tick infection rates were 30%.[7] Because of public fear of Lyme disease and a lack of regional data on the likelihood of tick bites by *I. dammini*, physicians in regions with any Lyme disease risk may consider antibiotic treatment of all tick bites. But in areas recently colonized by *I. dammini*, or at the edge of its range, the risk of Lyme disease following tick bites may be negligible because of limited distribution and a low population density of *I. dammini*.

From 1985, when the deer tick was first identified in Maine,[8] through 1989 there have been only 14 reported cases of Lyme disease acquired in Maine that meet the Centers for Disease Control's case definition. Most cases have been reported from two counties in southwest coastal Maine. Although deer ticks have been found in many coastal areas of the state, only these two counties were considered endemic areas for Lyme disease in 1989 by the Centers for Disease Control. This study characterizes tick species that parasitize humans in Maine, an emerging area of Lyme disease with a low prevalence of infection.

Materials and Methods

As part of a multifaceted study of *I. dammini* distribution in Maine, the Research Laboratory at the Maine Medical Center and the Maine Department of Conservation Insect and Disease Laboratory collaborated on a study of human parasitism by ticks during 1989 and 1990. Requests for ticks were publicized in brochures, public health notices, and the media. Individuals bitten by ticks in Maine were encouraged to save the ticks in alcohol and submit them for identification to either laboratory. The bite victim's name, age, and address; the data and locale of the bite; and any associated symptoms were requested. All ticks received were examined under a dissecting microscope and identified according to standard keys and taxonomic references.[9–13] All ticks submitted to state agencies were identified by the state entomologist; specimens received at the Maine Medical Center Research Laboratory were identified by research personnel with training and experience in tick identification (E.H.L., R.P.S.). Unusual specimens were submit-

This paper was submitted to the journal July 9, 1990, and accepted with revisions May 7, 1991.

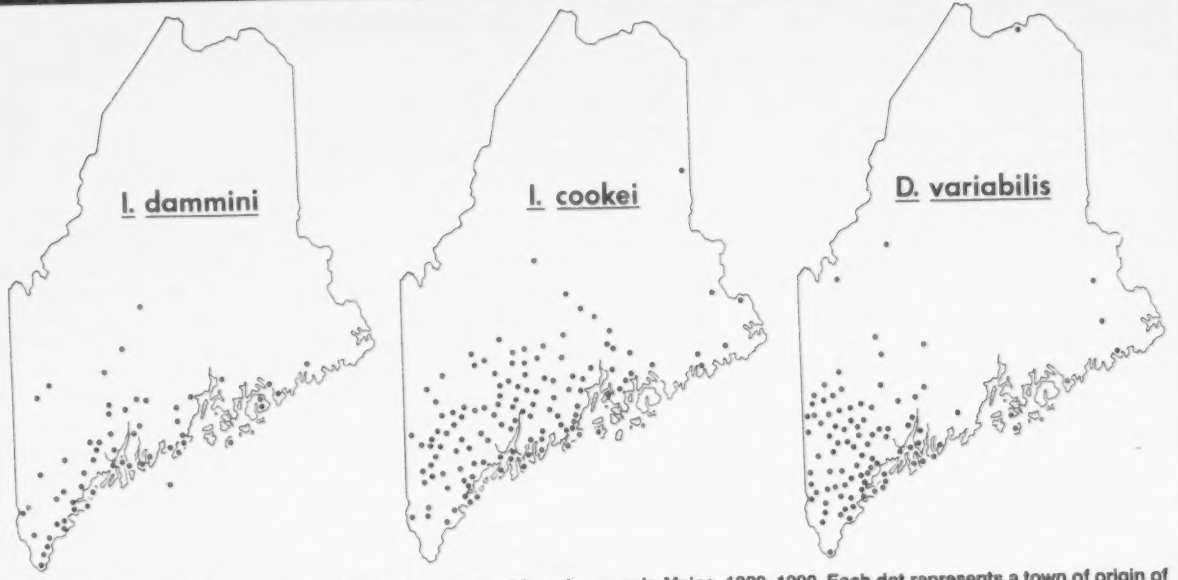

FIGURE 1—Distribution of common tick species removed from humans in Maine, 1989–1990. Each dot represents a town of origin of identified ticks.

ted to Dr J. E. Keirans, Smithsonian Institution, for confirmation of species identification.

Results

A total of 709 ticks that had been removed from 646 humans in Maine were submitted for identification. Ninety percent of all *Ixodes* ticks had been attached at time of removal. Although submitted ticks were received from residents of all of Maine's counties, few specimens were sent from northern areas (Figure 1). In the two known endemic counties, only 13% of ticks removed from humans were *I. dammini.* Of all *Ixodes* ticks submitted from these counties, 43.7% were *I. dammini*, compared with 26.3% in the remaining counties.

Tick species and stages are listed in the Table. Distribution of biting ticks of common species is shown in Figure 1. Seasonal distribution of tick bites by species is illustrated in Figure 2. The ages of tick bite victims ranged from 1 month to 89 years. Fifty percent of the *Ixodes cookei* ticks were removed from children under 16 years old, as opposed to 23% of *I. dammini* (odds ratio, 3.38 [95% confidence interval, CI, 2.05–5.57], $P < .001$) and 28% of *Dermacentor variabilis* (odds ratio, 2.52 [95% CI, 1.74–3.65], $P < .001$).

Ticks Removed from Humans in Maine, 1989–1990

	Hosts (n)	Ticks (n)	Larvae	Nymphs	Adults

D. albipictus	6	8	5	3	—
Total	646	709	31	219	459

Discussion

Tick surveys of deer and small rodents in Maine document the presence of *I. dammini* in widely dispersed coastal sites.[14,15] In contrast to reports from areas in which Lyme disease is highly endemic, however, this study demonstrates that *I. dammini* accounts for only a minority of tick bites in humans, even in the two Maine counties recognized as endemic in 1989. Sampling bias due to a low level of vigilance for small ticks could underestimate the abundance of *I. dammini* in an emerging area for Lyme disease, and such a bias is suggested by a low ratio of nymphal to adult *I. dammini* in this study.[1,2] However, the most common *Ixodes* tick species in our survey, *I. cookei*, is similar in size to *I. dammini*, and numerous specimens of the nymphal and larval stages of this tick were submitted.

Given the small proportion of tick bites due to *I. dammini*, the potential for exposure to Lyme disease from a tick bite in Maine is very low. As disease transmission requires attachment for 24 hours or more, many bites by disease-carrying ticks will not result in infection if the tick is removed.[16,17] One study in an area in which Lyme disease is highly endemic did not show a clear benefit from antibiotic treatment of deer tick bites, with only one of 30 untreated bites resulting in disease.[7] A second epidemiologic study of Lyme disease in outdoor workers, however, suggested a protective effect from incidental antibiotic use during summer months.[18] Our study demonstrates striking regional differences in the likelihood that a tick bite is due to a deer tick and supports the need for caution in applying results from studies in highly endemic areas to regions of lower prevalence of Lyme disease.

In contrast to previous surveys in the northeastern United States, this study documents frequent human parasitism by *I. cookei*, the "woodchuck tick." This small tick feeds on medium-sized mammals and cannot be distinguished from *I. dammini* without the aid of a dissecting microscope.[19–21] It has been reported as a

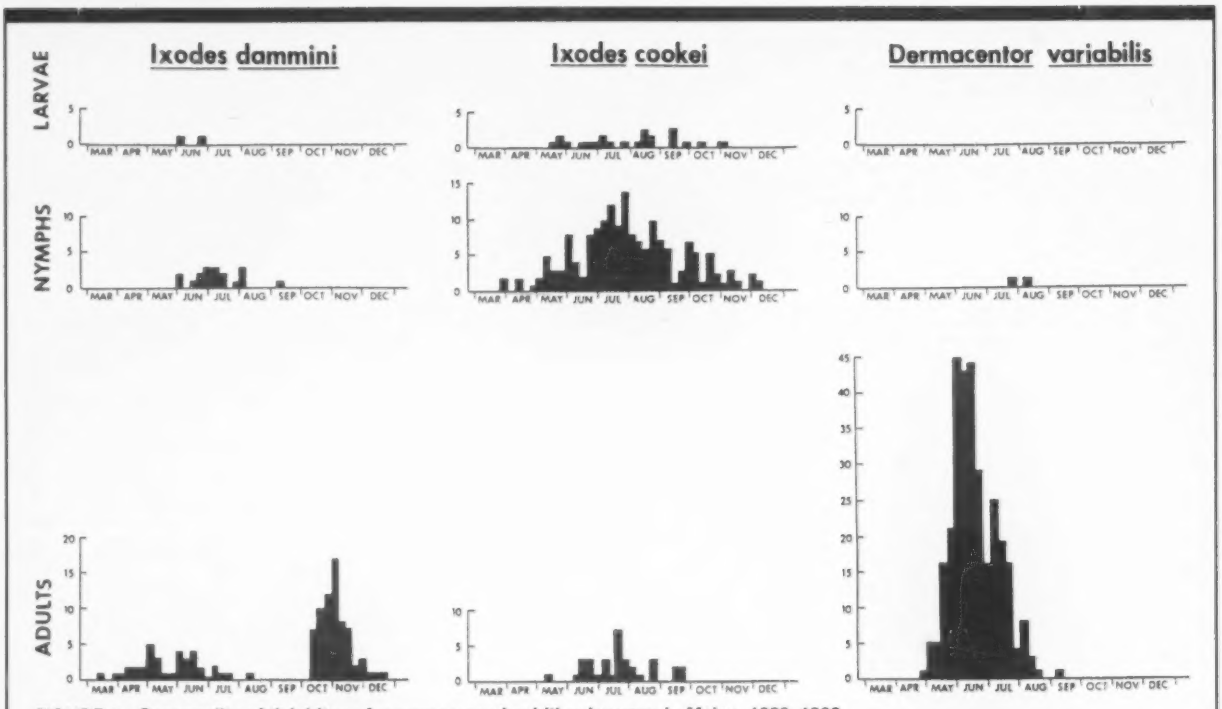

FIGURE 2—Seasonality of tick bites of common species biting humans in Maine, 1989–1990.

common cause of tick bites in Ontario, but has rarely been found to parasitize humans in other studies.[1,2,22] Although *B. burgdorferi* infection of *I. cookei* has been documented in a few tick specimens,[23] the role of this tick as a possible vector of Lyme disease has not been well studied. Unlike *I. dammini*, in its immature stages *I. cookei* does not parasitize mice.[20] *I. cookei* is a vector of Powassan encephalitis, a Group B arbovirus disease reported from upstate New York and Canada,[24,25] but not from Maine. Powassan encephalitis, although rarely diagnosed, can cause meningoencephalitis and radiculoneuritis with a spectrum of symptoms that could be confused with neurological complications of Lyme disease.[25–27]

Other small *Ixodes* species (*I. muris, I. marxi*) occasionally parasitized humans in Maine. *I. marxi* is another known vector of Powassan encephalitis.[21] The vector competence of both of these species for *B. burgdorferi* is unknown. *I. muris* feeds primarily on small rodents and could theoretically be an occasional vector of Lyme disease to humans.[28] Another mouse-feeding tick, *I. angustus*, has been cited as a vector of Lyme disease in one case report from the northwestern United States.[29] Despite its abundance on mice and red-backed voles in Maine, no examples of human parasitism by this tick were documented. *I. angustus* appears to be an unimportant vector of Lyme disease to humans in the northeastern United States.

D. variabilis, which accounted for 45% of bites, is widely distributed in southwestern Maine.[30] *D. variabilis* ticks may occasionally be infected with *B. burgdorferi*, but laboratory studies indicate that they are an ineffective vector of the disease.[31] *D. albipictus*, which is host specific for deer and moose, rarely bites humans but was in fact detached from one deer processor. It is not known to be a vector of disease to man.

Marked differences in the seasonal activity of tick species are illustrated by this study. In Maine, as in other areas of the northeastern United States, humans were parasitized by *I. dammini* nymphs in early summer and by adults in late fall.[32] The presence of biting *I. dammini* adults in late fall is of possible epidemiologic importance and may account for a bimodal peak of Lyme disease incidence reported in two previous studies.[5,33] Also of interest was the sporadic presence of biting adult deer ticks throughout the spring and summer months. These adult deer ticks, when engorged, may overlap in size with unengorged adult *D. variabilis*, for which they were sometimes mistaken by physicians. *I. cookei* infestation occurred throughout the summer, with no relationship between tick stages and month of bite. Ticks removed from humans in August and September, when active *I. dammini* are predominantly larvae, were almost exclusively *I. cookei*.

To the extent that they demonstrate changes in the abundance of *I. dammini* in emerging areas over time, surveys of human parasitism by ticks provide essential information for the development of regional public health policy regarding Lyme disease. In addition, tick identification services may highlight unexpected vectors, such as *I. cookei*, that may be the cause of other infectious diseases that could be mistaken for Lyme disease. However, because the diversity and abundance of tick species may vary markedly over small areas, depending on the presence or absence of appropriate host animals, habitat type, and other factors, the risk of exposure to Lyme disease from tick bites may vary substantially at different sites in the same region.[36]

This study underscores the need for caution in the identification of tick species. Although the majority of "small" ticks biting people in some areas of the northeastern United States may be *I. dammini*, this is clearly not the case in Maine. The identification of different tick species in the *Ixodes* genus depends on the recognition of subtle morphological differences and

requires training and experience. A lack of government and academic support for arthropod biosystematics has contributed to the paucity of entomologists or others with these skills.[37] Effective regional tick surveys, therefore, may require cooperative arrangements between state health personnel and entomologists at colleges and universities, or others with training in tick identification. □

Prevalence of Human T-Lymphotropic Virus in Civilian Applicants for the United States Armed Forces

Chester R. Roberts, PhD, Donald R. Fipps, MS, John F. Brundage, MD, Stephen E. Wright, MS, Mary Goldenbaum, MS, Steven S. Alexander, PhD, and Donald S. Burke, MD

ABSTRACT

Background. The wide range in human T-lymphotropic virus (HTLV) seroprevalences reported worldwide has made estimates of seroprevalence difficult in unique populations. In this study, the seropositivity of young adult civilian applicants for the US Armed Forces was determined.

Methods. Serum samples from nine geographic regions were screened by an Enzyme-Linked Immunosorbent Assay (ELISA), and repeatedly reactive samples were further tested by Western blot and radioimmunoprecipitation. Specimens were scored as positive when antibody to *gag* (p24) and *env* (gp46 or gp68) were detected.

Results. Of the 43 750 samples analyzed, 18 were positive for HTLV antibodies. Ten (55%) were from males and eight (45%) were from females. Nine (90%) of the males and seven (87.5%) of the females were Black. Twelve of the positive samples (66.6%) were from the New York City region, which represented only 18.8% of the sample population.

Conclusions. The overall HTLV seroprevalence of civilian applicants for the US Armed forces was 0.41 per 1000. This was higher than the seroprevalence reported for volunteer blood donors. (*Am J Public Health.* 1992;82:70–73)

Introduction

The human T-lymphotropic viruses type I (HTLV-I) and type II (HTLV-II) are retroviruses that are being detected in a wide variety of populations. It is likely that the virus is transmitted in several ways, including through contaminated blood products, exposure to contaminated devices used for illicit intravenous drug use, colostrum ingestion, and sexual contact. Two well-characterized, albeit rare, clinical conditions that result from HTLV-I infection are adult T-cell leukemia and tropical spastic paraparesis. Acute development of these conditions has not been documented; rather, clinically overt signs of disease appear to develop many years after infection.[1–3] Although seroconversion related to blood transfusion is well documented, there have been no reports of clinical manifestations or development of ATL directly associated with exposure to infected blood or blood products.[4] HTLV-II has not been firmly established with any clinical syndromes.

The prevalence of HTLV antibody has been studied in many different areas of the world. The southern islands of Japan appear to have some of the highest prevalence rates. Surveys have reported the following high prevalences among adults in these areas of Japan: Nagasaki, 37%; Kagoshima, 24%; and Okinawa, between 10% and 51%.[5–7]

Hawaiian-Japanese emigrants from high-prevalence areas have a reported prevalence rate of 20%.[8] In the Caribbean, the rate in Martinique blood donors was reported as 4.0%.[9] Studies of intravenous drug abusers who shared needles showed prevalences that varied from 9.0% in New York[7] to 64.6% in Rome.[10] Prevalence studies in presumed low-risk populations in the United States have shown a wide range of HTLV seropositivity: for example, seroprevalence rates were 2.1% in Georgia[7,11]; 0.5% in Florida[11]; 1% to 1.4% in Burlington, Vt[12,13]; 0.5% in Washington, DC[7]; 4.2% in Houston, Tex; and 3.8% in Birmingham, Ala, in blood donors over 30 years old.[12] An American Red Cross study of 39 898 blood donors from eight geographical areas in the United States showed a prevalence rate of 0.025%.[14,15] All of these blood donors were asymptomatic.

The wide range of HTLV seropositivity reported in these studies made it important to investigate the prevalence of detectable antibody to HTLV in civilian applicants for the Armed Services of the United States of America. These data would be critical to enable health care planners and providers to assess the impact of HTLV seroprevalence on health care operations.

Locations from which Sera were Collected for HTLV-I/II Antibody Seroprevalence Tests

Geographic Area	Number Sera	Number HTLV-Positive
New York, NY	8239	12
Baltimore, Md	7925	3
Cincinnati, Ohio	3249	0
New Orleans, La	5602	0
San Juan, Puerto Rico	2694	1
Fargo, ND	1800	0
Honolulu, Hawaii	1379	0
Miami, Fla	4196	1
Oakland, Calif	8666	1
Total	43,750	18

Methods

Population

Specimens for this study were a collected subset of samples of serum screened for human immunodeficiency virus (HIV). The specimens were collected at nine selected geographic regions from civilian applicants for the Armed Services of the United States between March 1988 and August 1989 (see Table). For this survey, specific identifier information (i.e., name and Social Security number) were unlinked from the specimen in order to ensure confidentiality.

Since HTLV-I/II and HIV-1 have similar modes of transmission, it was assumed that HTLV-I/II prevalence would mirror HIV-1 prevalence.[16] Therefore, the New York City, Baltimore, and Oakland regions were selected because of the high prevalence of HIV-1 in these geographic areas. Cincinnati, Ohio, was studied as an intermediate control with a 0.44 per thousand HIV-1 prevalence rate. Fargo, ND, was used as a negative control, because during the past 2 years, not a single Western-blot–positive HIV-1-infected individual has been processed through that region. The New Orleans region was selected because of reports that intravenous drug abusers in that community have a higher prevalence of HTLV-II and are not coinfected with HIV-1.[17] Honolulu was selected to determine whether applicants have increased prevalence rates because of Japanese influence. Miami and San Juan, Puerto Rico, were selected to determine whether applicants being processed from the Caribbean basin have an increased prevalence rate.

Serology

The screening test used to detect antibody to HTLV was a qualitative enzyme-linked immunosorbent assay (ELISA), obtained from the DuPont Company, Wilmington, Del. All repeatedly reactive samples were tested using the Western blot method (Biotech Research Laboratories, Inc, Rockville, Md). A blot clear of any bands, or containing bands seen where viral proteins do not migrate (nonspecific banding), was considered nonreactive. Blots were considered reactive when a gp46 (*env*) band and a p24 (*gag*) band were seen. The presence of viral bands in any combination other than the aforementioned pattern was considered nondiagnostic. All repeatedly reactive specimens were also subjected to a radioimmunoprecipitation assay (RIPA) performed by Biotech Research Laboratories, Rockville, Md. The HTLV antigen used in the RIPA was prepared from the MT-2 cell line. The presence of a band at 68 000 Da was considered reactive for antibody specific to the *env* protein of HTLV-1. In addition, the specimens were subjected to testing for the presence of antibodies to the recombinant HTLV-1 envelope protein known as 21E.[18] This included testing by an ELISA obtained from Cambridge Bioscience Corporation, Worcester, Mass, and by a Western blot performed by Biotech Research Laboratories, Rockville, Md.

Specimens were scored as positive when antibody to *gag* (p24) and *env* (gp46 or gp68) could be demonstrated by Western blot alone or in combination with RIPA. Due to the cross-reactivity of anti-HTLV-II antibodies in all of the above serological methods, positive specimens may be due to either HTLV-I or HTLV-II.

Results

In the overall study population (see Appendix), 82.6% (36 138) were male and 17.4% (7612) were female. Approximately 53% of the study group were less than 21 years old. The majority of the applicants (53.9%) were White, followed by Black (26.7%) and Hispanic (12.1%). Several applicants (7.3%) selected "other" as their ethnicity. Although the study applicants were processed through the nine geographic regions sampled, they represented some 40 different states and US territories.

A total of 43 750 specimens were screened during the study period, and 285 were found to be repeatedly reactive for a total ELISA repeat reactive rate of 6.51 per thousand. Prevalences of repeat reactivity varied among study sites, from 0.18 (Honolulu, Hawaii) to 1.51 (New York City, NY) per thousand. Of the 285 repeat reactives, 119 (41.8%) were nonreactive, 158 (55.4%) were nondiagnostic, and 8 (2.8%) were reactive by Western blot. All these specimens were also tested by RIPA. The RIPA was able to demonstrate *env* protein (gp68) on all eight of the reactive blot samples, 10 of the nondiagnostic samples that also had a p24, and none of the nonreactive blot samples. Therefore, using the criteria discussed above, 18 specimens were confirmed as positive. The overall prevalence for detectable antibody to HTLV-I/II in this sample of civilian applicants for the US Armed Forces was thus determined to be 0.41 per thousand. Of the positive applicants, 10 (55%) were male and 8 (44.5%) were female. Nine (90%) of the males and 7 (87.5%) of the females were Black. The overall prevalence among Blacks was 1.37 per 1000. One of the Black females was also HIV infected. The youngest male was 18 and the oldest was 43, with the average age being 28.0 and the median age being 22. The youngest female was 20 and the oldest 47, with the average age being 28.5 and the median age being 24. Twelve of the positives (66.6%) were from the New York City region, which represented only 18.8% of the sample population. Since 895 000 individuals volunteered for military duty during the study period, if we assume that this study is representative of those volunteering for military duty it can be estimated that over 260 HTLV-I/II infected individuals entered the military service between March 1988 and August 1989.

Discussion

In a recent report on 39 898 American Red Cross volunteer blood donors, Fang et al. reported an initial reactive rate to HTLV-I of 0.44% and a repeat reactive rate of 0.17%.[14] Our repeat reactive rate of 0.65% among civilian applicants for the military was 3.8 times higher than that among volunteer blood donors. This may have been due to the different screening ELISAs employed. However, the prevalence of confirmed positives (0.41 per thousand) among civilian applicants was 1.6 times higher than that among volunteer blood donors. This finding starts to quantify the view that the prevalence of

HTLV-I/II in blood donors significantly underestimates that in the general population.

Determining HTLV-I/II antibody status will help define the epidemiology of the disease. More importantly, it may prevent HTLV-positive individuals from passing the virus to sexual partners and to newborn infants through infected mother's breast milk, and will exclude infected blood and blood products from blood bank inventories as well. For example, in Japan, the seroconversion rates to HTLV-I due to blood transfusions were reduced from 53.6% to 0.9% by removing seropositive blood products from the inventory.[19] Although detecting blood infected with HTLV-I or any retrovirus and removing it from the inventory is for the protection of the intended recipient, the notification, counseling, and access to health care benefits of the infected individual are equally important. When the demographic data of the 18 positive samples are compared with those of the overall study population, some surprising contrasts are apparent (see Appendix). Although only 17.4% of the study population were female, almost half (44.5%) of the HTLV-positive individuals were female. The prevalence among females was almost four times greater than that among males. Black applicants represented 26.7% of the study population but 88.8% of the HTLV-positive samples. The prevalence among Blacks was more than 30 times greater than that among whites. These relationships are based on unstable estimates and are confounded by geographic region. Still, they may provide some insight regarding the current distribution of risk among young adults in the United States.

For a number of reasons, the population in this study cannot be considered an unbiased sample of the general US population. The study subjects were not geographically representative, either by region or area (urban vs rural), of the US population. The general population in the United States is not 82.6% male, or 26% Black, nor is 53% of the population less than 21 years old. Several studies have shown that the prevalence of HTLV-I increases with age of population.[6,11,20–22] As the majority of the study population was under 21 years old, the true prevalence of infection in general is likely to exceed that reported here. In addition, this sample excludes individuals who have been convicted of a felony and those who are overt users of illicit drugs. This sample also probably underrepresents those who know or suspect that they are infected with HIV-1 (e.g., those identified as HIV-1-positive as blood donors through alternative test sites). For these reasons, the prevalences of antibodies found in this survey almost certainly underestimate the actual prevalences of HTLV-I/II infection in the general adult population from corresponding regions of the United States. However, from these data, one can estimate that the total HTLV-I/II-positive population currently entering the Armed Forces would be approximately 230 per year, providing recruiting numbers remain constant at approximately 564 000 per year. For health care planners and providers, HTLV infection would have a minimal impact on health care resources in comparison with other diseases of military importance. □

Correlates of Using Mental Health Services: Implications of Using Alternative Definitions

David Mechanic, PhD, Ronald J. Angel, PhD, and Lorraine Davies, MA

ABSTRACT

Background. Studies using varying definitions of mental health visits result in widely divergent estimates. This analysis examines the stability of a predictive model using three varying definitions based on provider type, diagnosis, psychotherapy, and psychotropic medication use.

Methods. Interview and questionnaire data and claims records from the RAND Health Insurance Experiment are used to test these models among 3138 enrollees.

Results. Estimates of visits, and factors associated with them, are highly sensitive to definitions. Depression was the only symptom/life situation variable, and education the only sociodemographic measure, predictive across all three models. Risk indicators such as suicide thoughts and drinking problems were only significant for the traditional (mental health specialty) model. While patients within the traditional model definition were significantly younger than other enrollees, those within the model using the most expansive definition were significantly older. Varying the definition also led to different results in respect to experimental manipulations, geographic sites, and some specific types of comorbidity.

Conclusions. A reasonable definition, consistent with medical standards, requires, at least, a mental health diagnostic judgment and some form of psychotherapeutic or drug treatment. Studies of the content of mental health care are needed. (*Am J Public Health.* 1992;82:74–78)

Introduction

Many studies report a high prevalence of psychiatric disorder, particularly depression and anxiety, among patients treated in the general medical care sector.[1,2] One goal is to understand help-seeking patterns among persons with psychiatric need, to understand how physicians recognize psychiatric morbidity in their patients, and to determine how to better educate clinicians to appropriately identify and treat psychiatric disorder.[3,4] A large proportion of patients with depression in general medical care are undetected, probably more than half.[5] Depressive disorders, and even symptoms of depression short of the disorder threshold defined by the Diagnostic and Statistical Manual of Mental Disorders (DSM-III), are associated with considerable disability, comparable to or surpassing the disability associated with many serious medical conditions.[6]

In practice, data on the prevalence of psychiatric disorder in the general medical sector come from either small clinical studies of selected practice settings or large national data sets that are broadly representative but lack detail. The large data sets are a common source of estimates of psychiatric morbidity in medical contexts and of analyses of correlates of mental health use.

In major surveys such as the Epidemiological Catchment Area (ECA) study,[7] respondents having various psychiatric symptoms are asked whether they sought care for these symptoms and from whom. Information typically is not available on care actually provided or its intensity. For example, in the ECA study respondents were asked whether they talked about any problems they had with emotions or nerves that might have been connected to or in addition to the reason for their general medical care visit. This general response was then used as a basis for analyzing mental health use.

Analyses from the ECA study indicate that most people with a DSM-III diagnosis as assessed by the Diagnostic Interview Schedule have not sought care for their mental health problem in the prior 6 months, and among those who have, almost half received such care exclusively from the general medical care sector.[8,9] Persons with a mental health visit in the prior 6 months, relative to all respondents, were more likely to be young, White, female, and unmarried and to have had some college education. Such patients were also more, likely to use clinics, to have a regular source of medical care, and to be receptive to professionals.[10] An alternative source of data comes from log diaries completed by doctors, as in the National Ambulatory Medical Care Survey. In this survey the doctor is asked to record the patient's complaints, symptoms, or other reasons for the visit in the patient's own words, principal and other significant diagnoses, new or continued medications ordered or provided, nonmedication therapies such as psychotherapy and "other counseling," and the duration of the visit. Such data on instances of treatment are more detailed than those obtained in the ECA study but do not permit aggregation of visits by person.

The authors are with the Institute for Health, Health Care Policy, and Aging Research, New Brunswick, NJ.

This paper was submitted to the journal July 11, 1990, and accepted with revisions May 6, 1991.

Jencks,[11] using data from the 1980 National Ambulatory Medical Care Survey weighted to reflect the US experience, found that "3.3% of visits [in primary] care were assigned a mental reason for visit, 5.6% received a mental diagnosis, 6.8% received a psychotropic drug, and 3.2% received psychotherapy/therapeutic listening" (p. 1904). Aggregating all of these indicators, excluding duplication, results in an estimate of 11.6% of visits during the year in which there is some evidence of mental health content. The concordance of these indicators, however, is much less common. Only one half of 1% were affirmative on all four criteria and 1.79% included a mental health reason, a mental diagnosis, and either the notation of drugs or psychotherapy. Thus using the inclusive rule of meeting any criterion yields a mental health visit rate 6.5 times greater than a definition based on the presence of a mental health reason, a diagnosis, and mental health treatment.

The conservative criterion is too limited since it is well established that patients with psychosocial distress may disguise the reason for their visit, presenting instead various physical complaints to justify the consultation.[12] Including visits that lead to both a diagnosis and some type of treatment essentially doubles the proportion of mental health visits from 1.79% to 3.49%, accounting for 29% of the mental health visits under the most lenient definition. Estimates of mental health visits are extremely sensitive to the classification assumptions used.

Conceptually, a mental health visit might be said to occur when a patient consults a clinician for emotional or psychophysiological symptoms. The clinician assesses the problem and provides care in direct response to the patient's complaints. Some patients, however, are confused about the sources of their distress, or may deny emotional symptoms. Thus, mental health visits also may include instances where a physician recognizes a psychiatric/emotional problem and provides treatment in response to this assessment, irrespective of the patient's definition, presentation, or understanding of the problem. It would ordinarily be expected that the doctor would make some diagnostic judgment before treatment, but the data indicate that some doctors treat without recording a diagnosis. Several credible alternative definitions are possible. The purpose of this analysis is to examine the extent to which there is stability in predictive models of use of mental health visits when definitions vary.

TABLE 1—Most Common Patterns of Mental Health Care for Total Sample 18 Years and Older in the RAND Health Insurance Experiment

21	Yes	Yes	No	Yes

Note. The total number of adults was 1324 (including patterns not shown).

Methods

Procedure

Our data source is the RAND Health Insurance Experiment (HIE), a large experimental study with random assignment carried out between 1974 and 1982. The HIE studied the impact of varying schedules of coinsurance on medical care use and other outcome variables.[13,14] Subjects were followed for 3 to 5 years, depending on experimental assignment, and six geographic sites were included in the study. Independent measures were collected at baseline from interviews and self-administered questionnaires and were linked with subsequent claims forms recording types of practitioners seen, the primary problem or diagnosis as well as other problems/diagnoses for which physicians supplied treatment, procedures used, and drugs prescribed. Measures of morbidity, based on International Classification of Diseases codes, were derived from the claims information. The classification of psychoactive drugs is based on work by the RAND researchers,[15] who classified antipsychotics, antidepressants, and minor tranquilizers, using the National Drug Code Directory, excluding prescriptions when the record showed it was in response to a physical problem. Psychiatric procedures were classified following the California Relative Value Codes. Since the vast majority of procedures constituted psychotherapy, we refer to them as psychotherapy here. Comorbidity measures from the claims forms, and variables characterizing the experimental groups and geographic sites used in the study, are included as controls. We test a model including risk indicators (suicide thoughts, legal problems, deviant sexual behavior, and drinking problems), measures of health status and life situation (depression, a general health index, and life events), comorbidity measures, and sociodemographic variables. The theoretical relevance of the model and the specific measures used are described elsewhere.[16] Our purpose here is to examine the stability of prediction under varying definitions, and, thus, we do not dwell on specific substantive findings. Since some respondents participated in the experiment for 3 years, and others 5 years, a variable (TERM) is included to correct for different periods of exposure.

The RAND researchers did extensive developmental work to ensure the reliability and validity of key questionnaire items, particularly those involving health perceptions.[17] Summaries of major results and significant publications from the HIE are available.[18,19]

Descriptive data are based on 4403 persons aged 18 to 61 at enrollment. In the multivariate analyses, data from Dayton, Ohio, are excluded because this site was used to pretest the instrument and many of the items in the survey are not comparable between Dayton and other sites. This reduced the sample to 3739, of which 3138 had complete information on all variables. The multivariate analysis is based on these 3138 respondents.

Descriptive Data and Study Definitions

Tables 1 and 2 show the most common patterns of mental health care for adults and children during the experiment. These data allow differentiating care provided by mental health professionals such as psychiatrists, psychologists, social workers, psychiatric nurses, or other mental health practitioners as compared with general medical personnel. Using any of four criteria for a mental health visit (seeing a mental health provider, receiving

TABLE 2—Most Common Patterns of Mental Health Care for Total Sample 5–17 Years of Age in the RAND Health Insurance Experiment

18	No	Yes	No	Yes
16	Yes	Yes	Yes	Yes
14	No	Yes	Yes	No
13	Yes	Yes	No	No

Note. The total number of children was 287 (including patterns not shown).

a mental health diagnosis, receiving psychotherapy, and receiving a psychotropic drug for conditions other than those justified by physical symptoms [e.g., back pain]), 1324 adults had a mental health visit over the period of the experiment (30.1% of the eligible sample). Only 42% of these adults had visits in the specialty mental health sector over the life of the experiment. Nine patterns of care account for 97% of all instances of care. Most common were visits to a non–mental health specialist who prescribed drugs either with or without a mental health diagnosis and visits to a mental health specialist who made a mental health diagnosis and provided psychotherapy but no drugs.

One hundred thirty-eight children, aged 5 to 17, received care in the specialty mental health sector, 48% of the 287 children who used mental health services. Eight patterns accounted for 97% of all mental health care. Most common patterns were visits to mental health specialists who made a diagnosis and provided psychotherapy, visits to generalists who made mental health diagnoses but provided no specific care, and visits to generalists who did not make a diagnosis but prescribed drugs. All but one of the children without a diagnosis but treated with drugs were seen exclusively by general physicians.

The first two tables illustrate that there are numerous ways of classifying and aggregating mental health visits, and the conventions in the literature vary depending on the opportunities allowable with existing data sources. Most would concede that the numbers of visits will vary widely depending on the definition used, but it is generally assumed that analytic work examining factors associated with such visits will not be affected substantially by definitional conventions or variabilities. Yet we know that the factors affecting help seeking in general are different from those that predict particular sources of care.[20,21] In the analysis that follows, we examine how varying definitions of a mental health visit affect conclusions about the correlates of care.

Using four criteria (provider type, diagnosis, psychotherapy, and psychotropic medications), three alternative definitions were derived from the claims files. The first definition includes all visits to mental health specialty providers that involve a mental health diagnosis and treatment with either drugs or psychotherapy, the traditional definition of a mental health visit. Four hundred sixty enrollees met these criteria over the course of the experiment (10% of the adult sample of 4403). A second definition includes enrollees who received a mental health diagnosis and who received either drugs or psychotherapy. This definition conceptually fits the characterization of the de facto mental health system. Seven hundred sixteen enrollees (16.3% of the total sample) met these criteria. The third definition—the most inclusive—includes the 1027 respondents who received either psychotherapy or a psychotropic drug regardless of the provider or an explicit mental health diagnosis (27.5% of the total sample). Generalists often treat psychologically distressed patients without making a diagnosis, and these criteria constitute a more robust definition of the de facto system.

Results

Table 3 presents three logistic regressions that compare individuals who made mental health visits as defined by our varying criteria (traditional, de facto, and robust de facto) with those who did not have a visit based on these criteria. The results vary greatly depending on the way a mental health visit is defined. In the comparison involving those who met the traditional criteria (Model 1), mental health visits are associated with depression, suicide thoughts, and drinking problems. Persons making such visits also have more education, are younger, and are less likely to be Black. None of the other sociodemographic variables are statistically significant. Mental health visits as defined in Model 1 occur significantly more frequently in some plans and geographic sites than others. Patients with comorbidity involving infections, nervous system disorders, digestive and respiratory problems, and accidents are significantly more likely to have such visits.

Model 2 presents results for those who had a mental health diagnosis and received a psychotropic drug or psychotherapy. Only depression is significant among the risk and health status/life situation variables. Most of the insurance plans and two of the sites are also statistically significant. Education is the only significant sociodemographic variable, and several comorbidity measures are significant, as well as the control for length of participation in the experiment (TERM).

Model 3, based on the most inclusive definition of mental health visits, includes all respondents in either sector who received either psychotherapy or a psychotropic drug. In this model a mental health diagnosis is not needed to meet criteria for a mental health visit. Depression is associated with a greater probability of having a visit, whereas the measure of favorable perceptions of general health status is associated with a lower probability. Older enrollees and those with more education are significantly more likely to have such visits. Persons making mental health visits by this definition are significantly more likely to have most comorbid conditions than those without such a visit.

Discussion

Definitions of mental health visits vary in the literature. Our analysis shows clearly that estimates of the number of mental health visits, and the factors associated with them, are highly sensitive to these definitions. Depression was the only symptom/life situation variable and education the only sociodemographic measure predictive in all three models. Several measures of comorbidity were consistent predictors, reinforcing the general awareness that comorbidity is common in mental health care. Several of the experimental variables were also significant across the three models.

More pertinent were the many important variables that had varying effects depending on definition. Risk indicators such as suicide thoughts and drinking problems were related only to the traditional specialty model, and this was the only model that had significantly fewer Black patients. Model 1 had significantly more younger patients, while Model 3 had significantly fewer younger patients. Enrollees with a lower perception of their general health status were significantly more common in Model 3, but not in the other models. The models also gave significantly different results in respect to some of the experimental manipulations, geographic sites, and some specific types of comorbidity.

The RAND HIE did not include all of the important measures found in other use studies, but there is substantial overlap. The discrepancy in results among models, and with other findings in the literature, argues for great care in defining precisely what we mean by mental health use. One important conclusion that emerges from this analysis is the critical importance of an appropriate definition of mental health use consistent with planning needs.

In a related paper, Mechanic[22] suggested that very broad definitions of mental health visits inadvertently encourage a perception that seriously overestimates the responsiveness of the medical care system to persons with mental health needs. These definitions, and the data that support them, take on a life of their own. The traditional definition, as defined in this paper, is probably too narrow in that it neglects the valuable services provided by generalists, but the robust de facto model is probably too lenient for a realistic assessment of service provision. Model 2 is, at least, a beginning consistent with medical standards. It is reasonable to expect that a physician will make a diagnostic judgment before initiating mental health treatment, and such an assessment is required under Model 2. Continued use of such data sets should be supplemented by qualitative studies that examine in detail the content and appropriateness of mental health care. □

Booklets Help Hospitalized Patients Quit Smoking

Quitting smoking may be the last thing on patients' minds when they enter the hospital. Yet as more and more medical institutions go smoke-free, patients must stop smoking when they enter the hospital.

Two booklets designed by the Hopkins Hospital Smoking Cessation Service help patients quit smoking, both during the hospital stay and afterward. The booklets are now available to health care providers elsewhere and can be personalized with a particular hospital's name on the cover.

As the titles suggest, *Quit Smoking for Good . . . While You're in the Hospital,* and *Stay Quit for Good . . . After You Leave the Hospital* offer patients tips on kicking the habit in both settings. Each booklet uses simple language, humor, and cartoon illustrations in a sympathetic approach to guiding patients through the quitting process. The booklets can be used as tools for nurses, hospital admissions officers, and addiction specialists.

A third booklet, *Help Someone You Care About Stay Quit for Good,* intended for family and friends of patients who help support the patient's smoke-free lifestyle will be available in January 1992.

The cost is $2.05 per booklet (discount available for large orders). To order call 301/955-4155.

Evaluation of a Self-help Dietary Intervention in a Primary Care Setting

Shirley A. A. Beresford, PhD, Elizabeth M. Z. Farmer, MA, Lisa Feingold, MSPH, Karen L. Graves, PhD, Sheron K. Sumner, PhD, and Richard M. Baker, MD

ABSTRACT

Background. Dietary intervention to reduce fat consumption and increase fiber consumption has been recommended by the National Cancer Institute, but there is little evidence concerning the effectiveness of self-help materials. The purpose of this study was to evaluate such self-help materials, introduced by a nurse in a primary care setting.

Methods. A randomized controlled trial involving 242 subjects was conducted in two primary care clinics in Chapel Hill, NC, in 1987. Changes in fat and fiber consumption in the intervention and control groups during the 3-month interval between interviews were compared using analysis of covariance.

Results. The estimated reduction in fat was 3.8g larger for the intervention group than for the control group, but the confidence interval included zero. For those individuals who had some responsibility for meal preparation there was a larger difference (−6.9g) in favor of the intervention group, although the difference using calorie-adjusted values was −3.8g with a 95% confidence interval (−7.1, −0.4). The differences for fiber change were smaller.

Conclusions. We found significant small but consistent differential changes associated with a minimal self-help intervention, but we cannot rule out the possibility of some response bias. Nonetheless, this study demonstrates that the use of self-help materials for dietary change is feasible, and may be effective. (*Am J Public Health.* 1992;82:79–84)

Introduction

Dietary modification to reduce fat consumption and increase fiber intake is one of the main preventive interventions recommended by the National Cancer Institute (NCI). The NCI's goal is to reduce breast and colon cancer mortality through the reduction of fat intake to 30% of total calories or less and through the increase of fiber consumption from 8 to 12 grams per day to 20 to 30 grams per day.[1]

Although these NCI recommendations have generally been well accepted, there have been few studies evaluating the efficacy of a particular intervention in modifying dietary fat and fiber intakes. The Ludwig Institute (Toronto) is evaluating the recurrence rates of polyps in patients who are counseled to follow a very high fiber, low fat diet compared with the rates for those who are counseled to follow Canadian Government dietary guidelines.[2] The University of Minnesota has evaluated different intervention strategies to modify fat and fiber, including correspondence courses, community interventions involving media,[3] and individual counseling using educational materials.[4] Results from the Women's Health Trial Vanguard Study indicate that intensive group participation was effective in maintaining a reduction of dietary fat intake over a 2-year period.[5]

A review of the cardiovascular disease prevention literature reveals that it is possible to influence the diets of individuals at higher risk for heart disease.[6] Four randomized studies published in the period 1975 to 1984 targeted subjects' saturated fat consumption in an attempt to reduce their risk of cardiovascular disease, and evaluated the impact of interventions on dietary fat consumption.[7–11] All four were successful in lowering fat consumption to some degree. The program with the least intensive intervention appeared to be self-teaching using a slide projector.[10] A more recent study in group general practice in Britain found individual counseling to be effective in the short term in lowering plasma lipid levels in men.[12]

No evidence has been published to date concerning the efficacy of self-help written materials, as an alternative form of self-teaching, in achieving behavior changes in dietary fat and fiber intake, although there is evidence for the usefulness of self-help materials in smoking cessation.[13–15] If parallels to the behavior changes associated with smoking cessation can be drawn, it appears that the influence of the primary care physician can be a useful adjunct to self-help materials.[16–19] Before researchers can enlist physicians to provide advice about di-

etary modification to their patients in conjunction with self-help materials, it is necessary to assess the feasibility and efficacy of this strategy. The present study was designed to meet this need.

Materials and Methods

Study Population and Data Collection

A randomized, controlled trial of patient self-help materials introduced by a nurse was conducted in two primary care clinics in Chapel Hill, NC, in 1987. The study population included adult patients (over 18 years) seeing their primary care physicians. Patients with life-threatening conditions or mental illness that would render them unable to respond to questions were excluded. Clinic days (Monday through Friday) were randomly assigned to intervention and control designations, and allocation was balanced in 10-day blocks. Three hundred forty patients waiting to see their physicians were invited by a research assistant to participate in the study, 167 on intervention days and 173 on control days. Twelve patients refused to participate. Patients who agreed to participate were interviewed in a small room, close to the waiting area. The interview questionnaire ascertained demographic information including educational level and whether the respondent had a home telephone. If the respondent had less than an eighth-grade education or had no home telephone, he or she was judged to be ineligible and the interview was terminated. Twenty percent of the intervention group and 23% of the control group were so excluded. For eligible respondents, the interview continued and information on current dietary habits was obtained. Some respondents were called to see their physicians before the interview was complete. Most of these (all but 14) were able to complete the interview and talk with the study nurse, if appropriate, after their appointments. The number of subjects successfully enrolled in the study was 242, 120 (72%) in the intervention group and 122 (71%) in the control group.

Those attending the clinic on an intervention day received the packet of self-help materials, which was briefly introduced to them by the study nurse. The subjects were then free to see their physicians as scheduled. Subjects seeing their physicians on control days received the baseline interview only, and then saw their physicians in the usual way. For subjects in the intervention group, use of the self-help materials at home was reinforced via a telephone call from the study nurse at about 10 days. Information concerning the acceptability and use of the materials was collected at this time. Approximately 3 months after the initial contact, both groups of subjects were telephoned by the research assistant, who conducted a follow-up telephone interview that included a repeat assessment of current fat and fiber consumption and some new questions concerning food choices. The research assistant was not informed as to the group to which an individual subject belonged.

Intervention

The intervention in this study was self-help materials, introduced to the subject by a study nurse and reinforced later by telephone. This registered nurse was not a member of the health care team. The presentation by the nurse was limited to 5 minutes, to resemble the kind of time commitment feasible for primary care physicians. The self-help materials were developed by some of us (K. G., S. S.), revised to an eighth-grade reading level, and professionally printed in attractive folders with 15 card inserts of varying sizes to give the user easy access to different types of information. The self-help materials emphasized a healthy diet for all individuals, and focused on fat and fiber. The same information was presented in several different ways in the packet. Included in the packet were (1) a checklist to help the individual determine the extent to which he or she had made desirable changes in fat and fiber consumption; (2) a sample food record with a fat and fiber counter booklet to help determine exactly how much fat and fiber had been consumed; and (3) menus offering a variety of food choices to satisfy personal tastes while modifying fat and fiber intake to recommended levels. Information about the NCI guidelines was given.

Measurement of Outcome

The outcome of interest in this study is patients' dietary behavior with respect to fat and fiber intake approximately 3 months after an index visit to their physicians. The accurate measurement of dietary behavior has been a problem of concern to nutritionists and epidemiologists for a long time. Methods that can accurately classify an individual's dietary intake require a substantial commitment from either the interviewer or the individual respondent. For population studies linking dietary factors to disease, less accurate methods, which impose fewer demands on the interviewer and respondent, are acceptable.[20] These methods include the Semiquantitative Food Frequency Questionnaire (SQFFQ) developed by Willett,[21] which was used in the present study. This questionnaire has been validated against 4-day food records, a method that has greater face validity, both in a small group of healthy volunteers[22] and in 173 nurses.[23] Little information is available about the sensitivity of this food frequency method in detecting changes in diet that might be expected as the result of a dietary intervention. As with some physiological measures, such as systolic blood pressure, the within-person variability in dietary behavior may be at least as great as the between-person variability.[23] With this in mind, two classes of outcome measures were chosen in this study.

The first was fat and fiber consumption from the SQFFQ,[21] which was administered during an interview both at baseline and at follow-up. The values for fat, fiber, and calories for each food item or class of food items were estimated by one of us (S.S.), using the most recent analyses from USDA Handbook 8.[24] The analyses for the main study (described below) were then reworked, using the database and modifications developed by Willett[21] for fat and calories, and these analyses are presented here. There was a very high correlation between the two methods, and the results did not change substantially. For dietary fiber, the most recent data from Bowes and Church were used,[25] rather than Willett's database.

The second outcome measure was fat and fiber scores from a behavioral questionnaire designed to detect changes in food choices (as opposed to relative consumption in a population), which was administered at follow-up only. This behavioral questionnaire was developed from the checklist used in the self-help materials.

Validation Studies

Two validation studies were conducted to support the use of the instruments in this study. The first study examined the concordance of results obtained face to face and those obtained by telephone. Thirty-two ward clerks at North Carolina Memorial Hospital were asked to complete the SQFFQ on two occasions, 1 week apart. Complete information was obtained from 30. One occasion was an in-person interview (to mimic the baseline interview in the main study) and the other was a telephone interview. A crossover design was used to randomly allocate par-

ticipants to order of administration. Effects were computed by analysis of variance for split-plots.[26] Interactions between mode and period were assessed for both fat and fiber intake. There was no interaction between period and mode for either daily fat or daily fiber intake, and there was no significant difference due to mode. Indeed, the correlation between fat intake as assessed by telephone and fat intake as assessed face to face was of the same order as other test-retest correlations using the same mode of administration on two occasions, namely, 0.5.[22] On the other hand, there was a significant period effect, with responses to the first questionnaire indicating higher intake for both fat and fiber, regardless of mode of administration. This effect has been found in other studies.[27,28]

In a second validation study, the behavioral measure was compared with a 3-day food record (a near–gold standard measure of dietary intake) among monitor and division clerks at Moses H. Cone Memorial Hospital. Scatter plots and correlation coefficients were used to compare fat and fiber scores from the two measures. Twenty-nine ward clerks volunteered to participate. Summing the desirable responses ("always" or "frequently" for some questions; "rarely" or "never" for others) into a low-fat-behavior score and a high-fiber-behavior score resulted in scores ranging from 0 to 12 and 0 to 6, respectively. The low-fat-behavior score was moderately negatively correlated (as expected) with daily fat intake as assessed by both the SQFFQ (−0.44) and the 3-day food record (−0.31). The corresponding correlations between the high-fiber-behavior score and daily fiber intake were 0.47 and 0.45, respectively.

Statistical Methods (Main Study)

For the main study, the intervention and control groups' changes in fat and fiber consumption in the 3-month interval were compared. Descriptive analyses were conducted for daily fat and fiber consumption at baseline and at follow-up by examining the separate contributions to the daily total from different food groups. Responses to individual food-choice questions on the behavioral measure were also examined.

Analysis of covariance was used, with the follow-up value as the dependent variable and the baseline value as a covariate. Fat consumption was assessed both in grams and adjusted for calories consumed. The adjustment method[29] used simple linear regression coefficients of fat on calories at baseline for the baseline value and fat on calories at follow-up for the follow-up value. The simple regressions used data on all 189 subjects with complete information for caloric intake. A similar analysis was carried out for dietary fiber. Additional covariates were potential confounders such as age, education, gender, race, who prepared meals, household size, number of cigarettes smoked, miles from the clinic, and clinic, which were assessed for confounding and successively eliminated backward from the model. One non-Black non-White subject was excluded from these analyses. Variables that were significantly associated with the dependent variable or whose removal from the model caused a change of more than 10% in the partial regression coefficient for the group variable were retained in the model. The potential confounders age, education, gender, race, and who prepared meals were assessed as potential effect modifiers first, by including their interaction with group in the full model. All such two-way interactions were assessed together, using a chunk test.[30] Confounding variables in the final model were reassessed individually as effect modifiers by adding a two-way interaction term with group. A consistent set of confounders or potential confounders was sought for the different approaches to the analyses for fat and fiber. From the final models, the estimated group differences for change (follow-up minus baseline) were calculated for purposes of presentation, together with their 95% confidence intervals. Analyses were repeated, restricting observations to those whose follow-up interview was completed within 5 months of the baseline interview. Essentially the same results were obtained.

Similar analyses were conducted using total scores of desirable responses to the fat food-choice questions and the fiber food-choice questions that were part of the behavioral measure at follow-up. The behavioral measure was not used at baseline, so no adjustment could be made for baseline values. The validity of these analyses relies on the comparability of the two groups at baseline.

TABLE 1—Baseline Information by Group for Those Who Completed Follow-up

	Intervention (n = 93)	Control (n = 98)
Age, y	42	44
% Black	35	32
% Educated < 12 y	43	51
Fat (g)	66	67[a]
Fiber (g)	14	15
Fat/calories (%)	32	31[a]

[a]Based on one fewer observation.

Results

In the main study, the two groups of subjects appeared similar with respect to demographic and dietary intake information at baseline, and 78% of the intervention group and 80% of the control group completed the follow-up telephone interview. Those lost to follow-up in both groups included a higher proportion of Black respondents and those with less than a 12th-grade education. The baseline characteristics of those who completed follow-up in each group are shown in Table 1.

The baseline percentage of calories from fat is surprisingly low in both groups. Such an underestimation of fat calories was not found in the Moses H. Cone Memorial Hospital validation study, where the percentage of calories from fat was estimated at 39%, using data from either the food record or the SQFFQ. The participants in the Moses H. Cone study reported a higher frequency of consumption of baked goods than did participants in the main study, which could account for this discrepancy. In any event, the underestimates, if so they were, of fat calorie consumption in the main study applied equally to the intervention and control groups.

One hundred and ninety-one subjects, 93 in the intervention group and 98 in the control group, were followed up by telephone approximately 3 months after the baseline visit. The daily fat intake decreased between baseline and follow-up in both groups, and this decrease was accompanied by a decrease in kilocalories in both groups. Daily fiber intake in the control group decreased, on average, over the

TABLE 3—Adjusted Differences between Groups (Intervention − Control)[a]

	Group Difference	95% CI
Change in daily fat	−3.8 g	−9.4, 1.9
Change in calorie-adjusted fat	−2.0 g	−4.9, 0.9
Change in daily fiber	0.6 g	−0.9, 2.1
Change in calorie-adjusted fiber	0.9 g	−0.4, 2.1

Note. n = 190 randomized patients available for follow-up. Four individuals had missing values for covariates; one had missing values for fat and calories.
[a]Differences were adjusted for baseline value, miles from clinic, who prepared meals, and number of cigarettes smoked.

period of follow-up, while fiber intake increased in the intervention group.

Food choices, ascertained from the behavioral questionnaire at follow-up, are presented in Table 2. For all questions, the percentage with a desirable response was consistently greater in the intervention than in the control group. The greatest differences in behavior changes were observed in choice of cooking methods and choice of whole-grain breads or crackers. These changes were reflected in analyses of covariance examining number of low-fat behaviors (a maximum of 12) and high-fiber behaviors (a maximum of 6), adjusting for race, who prepared meals, and number of cigarettes smoked. The estimated group difference in low-fat–behaviors was 0.3 (95% confidence interval −0.4, 1.1); the difference in high-fiber–behaviors was 0.6 (95% confidence interval 0.1, 1.0).

The results of the main analyses of covariance are presented in Table 3. The estimated change in fat consumption in grams was 3.8 g larger for the intervention group than for the control group, adjusted for the four covariates, but the confidence interval included both positive and negative values. Generally, the results for both fat and fiber are not large, although they are consistent with a small change in favor of the intervention group.

There was some indication of possible effect modification with who prepared meals, so separate analyses were conducted for the subgroup that reported no responsibility for meal preparation and for the subgroup who reported shared or total responsibility. Those with no responsibility for meal preparation were a small subgroup (n = 43); the estimated group differences were small and the confidence intervals were wide.

On the other hand, for the larger subgroup of those with at least some responsibility for meal preparation, the estimated group difference after adjusting for baseline value and other covariates was −6.9 g, which was reduced to a difference of −3.8 g when calorie-adjusted values were used. The associated 95% confidence intervals are −13.2, −0.6 and −7.1, −0.4, as shown in Table 4. These estimates represent the greater decrease in fat intake in the intervention group beyond that in the control group over the period of follow-up.

Discussion

We found small but consistent differential changes in consumption of both dietary fat and dietary fiber over a 3-month period associated with a minimal self-help intervention. The differential change in fat consumption was statistically significant in the subgroup of respondents with full or shared responsibility for meal preparation. Indeed, it might have been expected that this subgroup would experience a larger differential change than those with no responsibility for meal preparation. The degree of differential change was of the same order of magnitude as that found among the husbands of the participants in the Women's Health Trial Vanguard Study,[31] namely, about 2% calories from fat. It is not surprising that this change is less than that found among the participants (the women) in the Women's Health Trial, since that intervention was rather intensive, consisting as it did of regular group sessions meeting over a period of 2 years.[5]

The participants in our study were not selected on the basis of risk for disease

or because they had a particular level of dietary fat or fiber consumption. Although potential subjects who had less than an eighth-grade education were excluded (because our intervention was based on written materials), a wide range of educational levels were included in the study. Those who were followed throughout the study were not substantially different from those who enrolled at baseline. The crossover validation study demonstrated that results from telephone administration of the SQFFQ are comparable to results from face-to-face administration with respect to fat and fiber consumption.

One of the limitations of the SQFFQ is that individuals tend to overestimate their consumption of a number of foods that are specified on the questionnaire. The instrument itself may lead to underestimation of nutrients because of the limited number of foods (152 items in 108 groups of foods) included on the questionnaire. It may be reasonable to assume that such overestimation and underestimation would be similar from one occasion to another, or from one group to another. Results from the validation study of ward clerks at North Carolina Memorial Hospital call into question the first of these assumptions, since it appears that the estimates of consumption were greater on initial assessment than 1 week later. The second assumption may also be questioned if, at follow-up, members of the intervention group are more aware of the desirable responses than are members of the control group, thus creating a response bias. The analysis of grams of dietary fat, adjusting for baseline responses, makes some adjustment for overreporting, but the analysis of calorie-adjusted values adjusts for general over- or underreporting directly at both follow-up and baseline. Arguably, greater weight should be placed on the estimates obtained using these calorie-adjusted values.

Because of the difficulty of measuring dietary behaviors of groups with sufficient accuracy that small changes in behavior can be detected, we used a number of different measures in this study. The consistency of the changes in favor of the intervention group, particularly with respect to dietary fat reduction, is striking. On the other hand, the leap of inference from finding changes associated with the intervention to attributing them to the intervention and concluding that it was effective in changing diet has to be made with caution. None of the outcome measures is free from potential response bias, and the measure of food choices, where evidence supporting differential changes in fiber consumption is strongest, is particularly liable to bias. The wording of the food-choice questions is fairly similar to that on one of the self-monitoring sheets in the package of self-help materials. Fabrication of responses to the SQFFQ would be harder.

Nonetheless, by using the public health approach of attempting to shift fat consumption down and fiber consumption up by small amounts in the whole population, we have demonstrated that the use of self-help materials for dietary change is feasible and may be effective. For such materials to be useful in primary care practice, they must be introduced to the patient by a member of the practice team during the normal course of an office visit; therefore, there is a need for a further study in which the influence of the physician or nurse or both is added to the intervention. Such a study is now in progress in western Washington. The results from this study should provide evidence about the benefits of a rather simple intervention that could easily be incorporated into the normal practice of a primary care clinic. □

TABLE 4—Adjusted Differences between Groups (Intervention – Control)[a] among those who had some responsibility for preparation of meals.

	Group Difference	95% CI
Change in daily fat	−6.9 g	(−13.2, −0.6)
Change in calorie-adjusted fat	−3.8 g	(−7.1, −0.4)
Change in daily fiber	0.7 g	(−1.0, 2.4)
Change in calorie-adjusted fiber	1.3 g	(−0.1, 2.7)

Note. n = 146 randomized patients available for follow-up who had some responsibility for preparation of meals; three individuals had missing values for covariates; one had missing values for fat and calories.
[a]Differences were adjusted for baseline value, miles from clinic, and who prepared meals.

Acknowledgments

This work was funded in part by the Centers for Disease Control's Prevention Centers Grant to the University of North Carolina (UNC). Portions of this manuscript were presented at the International Epidemiological Association meeting, Los Angeles, CA, August, 1990. We gratefully acknowledge the support of Dr Suzanne W. Fletcher and Dr Barbara S. Hulka during the development of this project, and of Dr O. Dale Williams as Director of the UNC Center for Health Promotion and Disease Prevention. We are grateful to Kathleen Welshimer, Kathleen Girardin, Sharon Campbell, Michelle Carnaghi, and Carolyn Dunn for their assistance with various parts of this project. Finally, we thank the patients and ward clerks of North Carolina Memorial Hospital and the ward clerks of Moses Cone Memorial Hospital, without whose participation the study would not have been possible.

American Journal of Epidemiology Corrects Its Press Release

"New Insights into Sudden Infant Death Syndrome," a news release published on p 1179 of the September 1991 issue of the *American Journal of Public Health* (Vol 81, No. 9) included an inaccurate statement.

Paragraph 5, sentence 2, as printed, reads: " 'The more common form of breech delivery called 'frank' presentation, with the baby emerging buttocks first, was not associated with an increased risk for SIDS,' Buck says." The corrected sentence reads as follows: " 'The sole control breech delivery was the more common delivery called 'frank' presentation, with the baby emerging buttocks first,' Buck says."

The original article, of which Germaine M. Buck, PhD, is the lead author, was published in the May 1, 1991, issue of the *American Journal of Epidemiology*. For questions, please contact the author at the Department of Social and Preventive Medicine, School of Medicine, SUNY at Buffalo.

Cigarette, Alcohol, and Coffee Consumption and Spontaneous Abortion

Ben G. Armstrong, PhD, Alison D. McDonald, MD, and Margaret Sloan, BA

ABSTRACT

We analyzed data from a survey of occupational factors and pregnancy outcome to examine the effects of cigarette, alcohol, and coffee consumption on pregnancy outcome. Clear and statistically significant associations were found between cigarette and alcohol consumption and spontaneous abortion. There was a weaker but statistically significant association with coffee consumption: If the associations were casual, 11% of the spontaneous abortions could be attributed to smoking, 5% to alcohol, and 2% to coffee. (*Am J Public Health.* 1992;82:85–87)

Introduction

An association of spontaneous abortion has been reported with smoking[1–3] and with alcohol,[3,4] but not with coffee. To study these relationships, we further analyzed data collected for a large study of occupational factors and pregnancy outcome.[5]

Methods

Some 56 000 women were interviewed, comprising all who had had a delivery or a spontaneous abortion in 11 Montreal hospitals in a 2-year period (1982 to 1984). Questions on occupational, personal, and social factors were asked for all recently completed (current) and all previous pregnancies. Details of the study design and methods have been fully described elsewhere.[6,7]

Among current pregnancies, the spontaneous abortions occurred to women treated in hospital, and thus were only a proportion of the total and not representative. Previous pregnancies, in which spontaneous abortions are more fully reported,[8] were used in these analyses. For each pregnancy, an inquiry was made about coffee, alcohol, and cigarette consumption during the first trimester. The numbers of cigarettes and cups of coffee per day and drinks of each type per week were recorded. In calculating total alcohol consumption, one and a half glasses of wine were taken as equivalent to a glass of beer or measure of spirits ("one drink").

All previous pregnancies were included, regardless of whether the woman was employed. Abortions induced for personal reasons or for fetal defect were excluded. Of a total of 48 582 previous pregnancies, 1436 were excluded because of missing information, leaving 47 146 for analysis. However, as questions on coffee consumption during previous pregnancies were introduced after the survey began, information on this factor was available for only 35 848 pregnancies.

Possible confounding by maternal age (at each pregnancy outcome), educational level, ethnic group, and employment during pregnancy was controlled by including these factors together with those under study in logistic regression analyses of spontaneous abortion risk. Allowance was made for dependence between the outcomes of successive pregnancies in the same woman by including the number of previous live births and spontaneous abortions as a risk factor.[9] Risks attributable to specific factors were estimated from logistic regression coefficients.[10]

Results

The overall rate of spontaneous abortion in previous pregnancies was 21.6%; it varied with the factors identified as potential confounders to the extent shown in Table 1.

After control for these factors, there remained a strong association of smoking habit with abortion risk (see Table 2), compatible with a linear trend on the logistic scale in which odds ratios increased by a factor of 1.20 (1.18–1.23) for each 10 cigarettes per day.

5–9	1 574	442	28.1	1.17	(1.03–1.32)
10+	499	154	30.9	1.19	(0.97–1.45)
All	47 146	10 191	21.6		

Note. OR = odds ratio, estimated by logistic regression with all factors, including age, pregnancy history, ethnic group, education, and employment status, in the model. CI = confidence interval.

The consumption of alcohol was also clearly associated with elevated risk; odds ratios increased on average by a factor of 1.26 (1.19–1.33) for each drink per day. The trend in risk was not smooth but rose abruptly between 0 and 1 to 2 drinks per week, leading to a significant departure from linearity ($P = .03$).

The risk by coffee consumption increased on average by a factor of 1.017 (1.004–1.030) for each cup per day; this trend was also statistically significant ($P = .01$).

Modification of these three effects by other variables (interaction) was systematically investigated. There were a few statistically significant interactions (smoking–age, smoking–alcohol, and coffee–gravidity), but their magnitude was small. Information on these interactions is available from the authors on request.

Discussion

The overall spontaneous abortion rate (21.6%) was high, even compared with that in other studies based on mothers' recall, in which the rates were around 15%.[11–13] This high rate may be explained by women's being more likely to plan further pregnancies after a spontaneous abortion than after a live birth; pregnancies preceding a current pregnancy will thus overrepresent spontaneous abortions.

The associations observed may have been affected by biases, despite the allowance made for many confounders. The retrospective nature of the enquiry could have led to biased reporting of the use of alcohol, cigarettes, or coffee, or recall of spontaneous abortion. The plausibility of such bias is somewhat controversial,[14] but the fact that these habits are not generally believed to be associated with abortion makes bias less likely. However, the abortions occurred somewhat closer in time to the interviews than did live births, so if recall was time-related, some bias might result.

The association observed between abortion and cigarette smoking is similar to that found in other studies, with magnitude of risk in the middle of the reported range.[1–3]

The risk associated with the moderate consumption of alcohol in the present study (a factor of 1.26 per daily drink) was less than those found in other studies; for example, one study found that risk increased by a factor of 2.33 for women drinking between two and six drinks per week,[4] and another found risk increased by a factor of 1.98 for one to two drinks per day.[3] Previous studies were either case-control with hospitalized abortions as cases,[4] or prospective, following women from their first antenatal visit.[3] Differ-

ences might thus be related to biases specific to the study designs.

The small risk associated with coffee consumption might be explained by residual confounding. If caffeine were a causal agent, we would have suffered loss of power from lack of information on other caffeine intake. However, nutrition survey data show total caffeine intake and coffee consumption to be highly correlated ($r = .98$) in Quebec women (Health and Welfare Canada, personal communication). Evidence of an association between caffeine consumption and early fetal loss has been reported,[15] but no such association has been reported, so far as we are aware, with spontaneous abortion.

If the observed associations were causal, cigarettes accounted for about 11% of all spontaneous abortions (40% in women who smoked 20 or more cigarettes per day), alcohol consumption for about 5% (45% in women drinking 3 or more drinks per day) and coffee for about 2% (16% in women drinking 10 cups per day). These risks warrant concern among public health professionals.

Cigarette, Alcohol, and Coffee Consumption and Prematurity

Alison D. McDonald, MD, Ben G. Armstrong, PhD, and Margaret Sloan, BA

ABSTRACT

We analyzed data from a survey of occupational and other factors in pregnancy to assess the effects of cigarette, alcohol, and coffee consumption on pregnancy outcome. The risk of low birth weight for gestational age was found to increase substantially with smoking. Occasional consumers of alcohol had a slightly reduced risk relative to total abstainers. In more frequent drinkers, there was a small increase in risk. Risk increased slightly with coffee consumption. (*Am J Public Health.* 1992;82:87–90)

Introduction

The reduction in birth weight that accompanies maternal smoking in pregnancy, first reported in the 1950s,[1,2] has been well established.[3,4] Studies of alcohol[5–12] and caffeine[13–16] consumption have given conflicting findings. We used data from a survey in Montreal of occupational and other factors in pregnancy to examine the effects of smoking and consumption of alcohol and caffeine on pregnancy outcome. The survey is described briefly in the first of this series of papers and in detail in earlier reports.[17–20]

Methods

The present analysis was confined to current (just-completed) single pregnancies. Of the 51 512 pregnancies, 10 364 were excluded because of factors known to affect length of gestation and birth weight: multiple pregnancy (475), induction of labor (6113), hypertension (1187), diabetes (154), and prenatal bleeding or illness (2435). For another 362 women smoking, alcohol, or coffee consumption were unknown, and for 341 outcome information was incomplete, leaving 40 445 pregnancies for analysis.

To separate factors that affect fetal growth from those that diminish length of gestation, we defined prematurity in three ways: (1) low birth weight (≤2500 g), (2) preterm birth (<37 weeks), and (3) low birth weight for gestational age (LBWGA; bottom 5%).

The overall rates among the pregnancies surveyed were as follows: low birth

weight 5.7%, preterm birth 7.0%, LBWGA 5.2% (Table 1). To investigate the dependence of these three measures on the factors of interest, we used logistic regression, adjusting for the confounding factors shown in Table 1.

Results

Smoking

The risk of all three measures of prematurity, especially LBWGA, was higher among smokers than nonsmokers, and increased with number of cigarettes smoked ($P < .001$) (Table 2). For every 10 cigarettes smoked per day, the risk of LBWGA increased by a factor of 1.51 (95% CI, 1.44–1.57). Smoking accounted for 39% of cases of LBWGA, 35% of cases of low birth weight, and 11% of preterm births.

We investigated risk according to changes in smoking habits only for low birth weight. Women who smoked before but not during the first trimester had no excess risk (Table 3). Risk was also consistently reduced in women who cut down their consumption. Cessation before the second trimester brought the risk close to that for nonsmokers (Table 4). It is less clear that continued but reduced consumption was associated with a reduction in risk.

Mean placental weight varied little with smoking. For nonsmokers it was 626.6 g; for smokers of 1 to 9 cigarettes daily, 617.8 g; for 10 to 19 cigarettes, 618.7 g; and for 20 or more, 614.8 g. Accounting for birth weight, the placentas of smokers were a little heavier than those of nonsmokers; for example, the adjusted mean weight for heavy smokers was 30 g more than for nonsmokers.

Alcohol

For all three outcomes, light consumers of alcohol had a small but statistically significant reduction in risk relative to total abstainers (Table 5). Risk then appears to increase with alcohol intake, especially for low birth weight ($P = .002$ for trend). We examined risk of low birth weight by type of alcohol. After controlling for number of drinks, we found that risk was higher by a factor of 1.24 (95% CI, 1.00–1.53) for beer drinkers, and by a factor of 1.38 (95% CI, 0.96–1.99) for drinkers of spirits, than for wine drinkers.

Coffee

Trends of increasing risk with coffee consumption were consistent for low birth weight ($P = .02$) and LBWGA ($P = .01$), reaching a peak at a factor of about 1.4 in women consuming 10 or more cups per day (Table 6). Risk of LBWGA increased by a factor of 1.04 (95% CI, 1.01–1.06) per cup of coffee per day. If these associations were causal, coffee would account for 6% of cases of LBWGA, and 4% of cases of low birth weight.

Interactions

Interactions between smoking, alcohol, coffee, and other variables were seldom substantial but often statistically significant ($P < .05$). For LBWGA, the risk of smoking was apparently greater for French-speaking women than for others by a factor of 1.55 (95% CI, 1.17–2.05); that of alcohol consumption was 1.35 times greater for mothers over 30 (95% CI, 1.08–1.69); that of coffee consumption was 1.27 times greater for alcohol consumers than for abstainers (95% CI, 1.02–1.60).

Discussion

A reduction in birth weight was found that was consistent with previous reports that infants of smokers weighed on average 150 to 250 g less than those of nonsmokers.[3] There was a quantitative relationship with the number of cigarettes smoked. Our exploration of interactions indicated that this relationship was not importantly influenced by any other factor. A slightly shorter gestation period, a mat-

ter of a day or two, was found in smokers in our study, as in others. The somewhat greater effect of smoking on birth weight corrected for gestation length than on uncorrected birth weight indicates that smoking directly retards fetal growth. The higher ratio of placental to infant weight that we found in smokers has also been observed by others.[21–23] Our finding that women who stopped smoking during the first trimester had little or no greater risk of having a low-birth-weight infant than did nonsmokers, together with other similar findings,[9,24,25] is important.

In contrast, the evidence for alcohol as a risk factor was unconvincing. Women who took fewer than seven drinks a week had fewer low-birth-weight babies than did those who drank more than this or those who drank no alcohol. This result is consistent with the finding of higher average birth weights in babies born to women who drank alcohol than in those who did not.[11] Two studies have been reported, one in Britain[7] and another in the United States,[8] in which retarded fetal growth was significantly more frequent when 10 or more drinks a week were taken. In France, an increase in small-for-dates babies was found among women who drank three or more drinks a day, but only in women who were mainly beer drinkers.[5] In our study also, such risk as there was predominantly affected beer and spirits drinkers. Our study and two others[9,26] suggest that there is no effect on birth weight when fewer than two or three drinks a day are taken, and that there is at most a small effect at higher levels of consumption. This conclusion remains compatible with the positive studies.[6,7]

The small increase in risk, with evidence of dose-response, suggests that heavy coffee consumption may have a small effect on birth weight. This finding is compatible with reported increases in risks by a factor of 1.24 for heavy coffee consumption[8] and by a factor of 1.58 for frequent coffee consumption.[16] In a study of total caffeine consumption, however, a fourfold increase in risk of low birth weight was found with the consumption of caffeine equivalent to more than three cups of coffee a day.[14] In Quebec women in the Canada Nutrition Survey, total caffeine consumption and coffee consumption were highly correlated (r = .98) (Health and Welfare Canada, personal communication). The difference between these two measures is thus unlikely to explain the higher risk found by the latter[14] study. □

Cigarette, Alcohol, and Coffee Consumption and Congenital Defects

Alison D. McDonald, MD, Ben G. Armstrong, PhD, and Margaret Sloan, BA

ABSTRACT

We analyzed data from a survey of occupational and other factors and pregnancy outcome to assess the effects of cigarette, alcohol, and coffee consumption. There was no evidence of an association between any congenital defect and smoking. Results for alcohol and coffee consumption were largely negative, but there was a weak association with musculoskeletal defects in babies born to women who drank one or more alcoholic drinks a day. (*Am J Public Health.* 1992;82:91–93)

Introduction

A report that smoking in pregnancy was associated with congenital heart defects[1] was not confirmed,[2-4] even in two large series of births.[5] Heavy alcohol consumption has been reported to cause retarded physical and mental development and certain facial and neurological abnormalities (fetal alcohol syndrome). Moderate alcohol consumption has also been reported to affect fetal growth and morphogenesis.[6] Some concern has been expressed that heavy coffee consumption may be teratogenic,[7] although a case-control study in Finland was negative.[8] We investigated the relationships between cigarette, alcohol, and coffee consumption and congenital defects, using data from a survey of occupational factors in pregnancy conducted in Montreal from 1982 to 1984 (see the first paper in this series). In this survey no association was found between congenital defects and chemical exposures estimated from job title,[9] but in a case-referent study an association with aromatic solvents was found.[10] The excess defects were mainly renal and urinary. The association of cigarette, alcohol, and coffee consumption with congenital defects has now been analyzed for all current and previous pregnancies of the 56 000 women interviewed—104 000 pregnancies in all.

Methods

The study design and methods are briefly described in the first of these reports, and have been described in detail elsewhere.[11] All current and previous pregnancies of more than 20 weeks' duration, whether or not the woman was employed during the pregnancy, were included in the present analysis. Therapeutic abortions for fetal defect were included irrespective of gestation length. Information on cigarette and alcohol consumption, and on potential confounding factors was available for 89 317 of these pregnancies. As questions on coffee consumption in previous pregnancies were introduced after the survey began, only 80 319 remained for study of this factor.

Congenital defects were ascertained (blind) in current pregnancies from pediatric records.[8] For previous pregnancies, the mother was asked whether any abnormality had been noted in the child. If a defect was suspected, further inquiries were made. The defects were classified into 90 groups. Minor abnormalities such as hydrocele, glandular hypospadias, undescended testes, skin tags, nevi, and hernias were omitted, as were known inherited defects, those that were poorly described (less than 1%), and those that became apparent only at a later stage of development, such as mental retardation, epilepsy, cerebral palsy, and deafness. Interauricular and interventricular septal defects were retained if accompanied by another heart abnormality. Cases with multiple defects were classified under the one that appeared to be most serious. Eight types of congenital defect (shown in Tables 1 and 2) were entered into the present analyses.

Possible confounding by maternal age, educational level, and ethnic (color and language) group was controlled by including these factors together with cigarette, alcohol, and coffee consumption in logistic regression analyses, which were performed separately for current and previous pregnancies. Regression coefficients for cigarette, alcohol, and coffee consumption from the two series were combined as a weighted mean to obtain a single odds ratio, as they did not significantly differ for any factor at a 5% probability level.

Results

There was no consistent evidence of an association between cigarette consumption and any defect group, after

[b]Rate per 1000 pregnancies.

accounting for possible confounding (Table 1). Odds ratios (relative to nonsmokers) for mothers who smoked one to nine cigarettes per day were 1.84 for neural tube, 1.53 for renal-urinary, and 1.14 for all defects. These values were on the borderline of statistical significance (at about $P = .05$); however, odds ratios were lower in heavier smokers.

There was some evidence of an increased risk of musculoskeletal defects in women who took alcohol, with risk increasing with the amount drunk (Table 2). The odds ratio of 1.82 in women who took seven or more drinks per week was significant at $P = .05$. Among the 13 defects in this group were 6 cases of congenital dislocation of the hip, whereas 2.3 were expected based on the proportion of musculoskeletal defects that were of this type overall. The specific risk for congenital dislocation of the hip (6/2.3 = 2.61) was thus somewhat higher than for musculoskeletal defects overall, but because of small numbers it is not statistically significant ($P > .05$). The other 7 musculoskeletal defects were craniosynostosis, scaphocephaly, cranial abnormality, hemivertebrae, limb reduction deformity (2), and fibular abnormality. Facial deformities were not observed.

Of the odds ratios for defects in babies born to coffee drinkers (Table 3), only that for heart defects among the children of women who drank three or more cups a day (1.52) was significantly elevated ($P = .02$). No specific type of heart defect was overrepresented in these 58 cases compared with defects in babies born to women who did not drink coffee.

Discussion

Given that over 70 odds ratios were tested, the three that were significantly ($P < .05$) raised could have occurred by chance. The one association with smoking, namely an increase of neural tube defects in babies born to women who smoked 1 to 9 cigarettes per day, would have been more convincing if an excess had been seen in the heavier-smoking groups. Even quite heavy cigarette smoking was common in this survey—in 30% of the pregnancies the mother smoked during the first trimester of pregnancy, and in 15% the mother smoked 20 or more cigarettes per day. Thus our study had the power to detect important risks due to smoking, if such risks were present. The risks we can exclude are specified by the upper confidence limits of the odds ratios, which are quite low for smoking.

Alcohol consumption, on the other hand, although perhaps underreported, was generally low. Only 3% of the women surveyed reported taking one or more drinks per day (seven per week), and 0.3% reported taking three or more drinks per day. The power of our study to detect increased risk at these levels was thus very limited, as is evident from the wide confidence limits for the odds ratios shown in Table 2. No case of suspected fetal alcohol syndrome was noted, although we were not specifically looking for the syndrome. The association of alcohol with musculoskeletal defects has not been reported elsewhere, and was of low statistical significance.

Coffee consumption was associated only with heart defects, and the evidence was not strong. In Finland, where coffee consumption is high (29% of those surveyed reported taking three or more cups of coffee a day, compared with 12% in Montreal), no association was found between coffee consumption and clefts of the lip and palate or defects of the central nervous, cardiovascular, or musculoskeletal systems. □

The Effect of State Cigarette Tax Increases on Cigarette Sales, 1955 to 1988

Dan E. Peterson, MD, MPH, Scott L. Zeger, PhD, Patrick L. Remington, MD, MPH, and Henry A. Anderson, MD

ABSTRACT

We evaluated the effect of state cigarette tax increases on cigarette sales in the 50 states for the years 1955 to 1988. State cigarette tax increases were associated with an average decline in cigarette consumption of three cigarette packs per capita (about 2.4%). Larger tax increases were associated with larger declines in consumption. Raising state cigarette taxes appears to be an effective public health intervention that can reduce cigarette consumption and its associated health consequences. (*Am J Public Health.* 1992; 82:94–96)

Introduction

Numerous studies have observed that cigarette consumption decreases when the price of cigarettes increases.[1–6] Although cigarette tax increases have generally been enacted to raise revenues, such tax increases have raised the price of cigarettes and are believed to have led to reductions in cigarette consumption. There was a substantial drop in national cigarette sales in 1983 following the increase of the federal cigarette excise tax from 8 to 16 cents on January 1, 1983. Several observers have commented on this as a cause–effect relationship.[7–11] It is likely that state cigarette tax increases, of which there have been 248 during the years 1955 through 1988, have had similar effects. In this context, we undertook the present study to assess changes in cigarette consumption following state cigarette tax increases and to quantify the amount of the change in cigarette consumption by the size of tax increase.

Methods

Annual data on cigarette packs per capita (number of packs sold in the state divided by the state's population), average retail price in the state, and state cigarette taxes were obtained from the Tobacco Institute.[12] Data were available from 1955 or when a state first imposed a cigarette tax, whichever was later. We converted all tax and price data to constant (1983) dollars.[13] Data on the enactment of state clean indoor air acts were obtained from the surgeon general's 1989 report.[7]

We defined the change in cigarette consumption for each state and each year as the difference between the sales in that state in the preceding year and the sales in the following year. Calculating the differences in sales for each of the states for each year of the study period gave us 1536 observations of changes in cigarette consumption. We adjusted for national trends in cigarette consumption by subtracting the national change in consumption for that year from each state value. This has the effect of controlling for national events, such as the 1983 federal tax hike, as well as national trends in sales due to such factors as national demographic trends and antismoking publicity.

To explore the effect of state tax increases on cigarette consumption, we compared changes in cigarette consumption for states in years with tax increases against states in years with no tax increase. We then categorized observations by the size of the tax increase and compared changes in cigarette consumption. We also categorized observations by the presence or absence of a new clean indoor air act and compared changes in cigarette consumption.

Means and standard errors of the categorized changes in cigarette consumption were computed. The standard errors were calculated using pooled estimates of the variance across subgroups, accounting for correlation among repeated events within a given state using the robust variance method of Zeger and Liang.[14]

After analyzing the data for the entire period (1955 through 1988), we looked at the effects in each of three time intervals: 1955 through 1964 (until the surgeon general's first report on smoking), 1965 through 1978 (when per-capita cigarette

TABLE 1—Change in Cigarette Consumption by State Tax and State Clean Indoor Air Act, United States, 1955–1988

	Change in Consumption (cigarette packs per capita)			
	1955–1988	1955–1964	1965–1978	1979–1988
Tax increase				
Yes	−3.0[a]	−3.3[a]	−3.8[a]	−1.5[a]
No	0.6[a]	0.7	0.7	0.3
Size of tax increase				
<4.0 cents	0.8	−0.9	6.9[a]	−0.6
>4.0–6.0 cents	−1.5	−3.8	−1.5	−1.2
>6.0–8.0 cents	−4.6[a]	−4.7[a]	−5.0[a]	−3.8[a]
>8.0 cents	−7.3[a]	−8.7[a]	−7.4[a]	−3.1
Clean indoor air act				
Yes	−0.1	...	−1.5	0.1
No	0.0	...	0.3	0.0

Note. Average capita consumption nationally for the period was 124.1 packs per capita (1955–1964, 119.5; 1965–1978, 126.6; 1979–1988, 125.0).
[a]95% confidence interval does not include zero

consumption peaked), and 1979 through 1988 (a period of declining consumption).

Results

Cigarette consumption declined by an average of 3.0 packs per capita in the 248 observations with a tax increase. In contrast, cigarette consumption rose by 0.6 packs per capita in the 1288 observations with no tax increase (Table 1). Stratification of the change in cigarette consumption by the size of tax increase yielded a clear dose–response relationship: the larger the increase in taxes, the larger the decrease in consumption (Table 1).

Regressing the size of tax increase on the change in cigarette consumption, we found that for each 1-cent increase in cigarette taxes, sales fell by 0.75 packs per capita (about 0.6%). Performing a separate regression on the data for each of the three time periods, we found that while in each period the effect of tax on sales was consistent and dose related, it appears that a given size of tax increase had less effect in recent years (sales fell by 0.85, 0.78, and 0.48 pack per penny tax increase for the time periods 1955 through 1964, 1965 through 1978, and 1979 through 1988, respectively).

No consistent relationship was found between the enactment of state clean indoor air acts and changes in cigarette consumption.

Discussion

Our results are consistent with the econometric literature on cigarettes, in which estimated price elasticity for cigarettes (the percentage change in sales as a result of a 1% change in price) has ranged from −0.14 to −1.44 depending on the methods used and the populations studied. Reviewing this literature, the surgeon general's 1989 report used −0.47 as an estimate of the price elasticity for the general population.[7] In our study, using a rough conversion from our tax-response format to an elasticity format, we found an elasticity of −0.49 (in this case the elasticity representing a sales decline of 0.49% for every 1% of cigarette price that the tax increase accounted for).

Despite the strong and consistent relationship observed, it could be argued that changing public opinion regarding smoking precedes and causes both a tax increase and a decrease in cigarette sales. This hypothesis seems unlikely, as we found the same relationship between tax increases and declines in cigarette sales even in the first period of the analysis, 1955 through 1964, a period before the surgeon general's first report and a time when little antismoking sentiment existed. Additionally, the enactment of a clean indoor air act, a similar legislative event that would seemingly also reflect such an underlying public opinion shift, was not found to be related to changes in cigarette consumption.

Other studies[4,5] have found some evidence for a relationship between enactment of a state clean indoor air act and reductions in cigarette consumption. We conclude, from our analysis, that if cigarette consumption declines occurred at the time of enactment of state clean indoor air acts, they were small compared with those seen with tax increases. Alternatively, state clean indoor air acts may have a delayed and more gradual effect on cigarette consumption, and may therefore have escaped our detection.

While our approach is conceptually easy to understand, it is limited in that we were not able to control for potential biases, such as state-to-state differences in sales or price trends, or to examine two effects simultaneously, such as the interaction of taxes and clean indoor air acts. To evaluate whether these limitations were an important factor in our results, we did a second analysis, using a longitudinal model,[15,16] in which we were able to control for state-specific trends over time and to examine the role of multiple variables simultaneously. The results of this second analysis were essentially the same as the first analysis. Restricting the analysis to 21 states reported to have little or no problem with bootlegging[17] (cigarettes purchased in one state and consumed in another) also did not change the results.

We have used an epidemiologic approach to evaluate the effect of a state-based public health intervention—the enactment of cigarette excise tax increases. Our results provide further evidence that state tax increases are effective in reducing smoking and that the larger the tax increase, the larger the drop in cigarette smoking. □

Mass Media–Led Antismoking Campaign Can Remove the Education Gap in Quitting Behavior

Petra Macaskill, MAppStat, John P. Pierce, PhD, Judy M. Simpson, PhD, and David M. Lyle, MBBS, PhD

ABSTRACT

This study investigated whether the effective mass media-led antismoking campaigns in Australia had the traditional differential effect across educational levels. Our population surveys included random samples of 12 851 people before the campaign and 11 609 several years after the campaign had started. No statistically significant differences were found in quitting across education levels in three of the four subgroups. Mass media-led antismoking campaigns may play an important role in getting the antismoking message to the less educated. (*Am J Public Health.* 1992;82:96–98)

Introduction

A major public health concern in developed countries is the increasing gap in smoking prevalence between educational groups.[1] In the United States, Canada, and Norway, smoking in the least educated groups is approximately twice as prevalent as in the most educated groups, and the rate of decline in smoking behavior is three to nine times lower.[2] Evidence indicates that those who are less educated obtain information from visual media (such as television) more often than those who are more educated.[3] If one barrier to less educated people changing their smoking behavior is the lack of access to motivational information,[4] use of a mass media–led antismoking campaign may reduce smoking prevalence overall without widening the gap between educational groups.

During the 1980s, mass media–led antismoking campaigns were conducted in two Australian capital cities, Sydney and Melbourne.[5,6] The Sydney campaign began in mid-1983, 1 year before the start of the Melbourne campaign. Using Melbourne as a control, Sydney showed a marked decline of 2.5% in smoking prevalence, a decline attributable to the campaign in the first year.[7] Subsequent results showed a similar decline in Melbourne in its first campaign year, and a continued decline over the next 4 years for men in each city.[8] Among adults, the decline in prevalence was primarily owed to quitting.[7]

During the years in which such campaigns were run, more than two thirds of the communities in both cities recalled television advertisements depicting the health consequences of smoking.[8] In this paper, we investigate whether the effects of this campaign differed by educational level.

Methods

A subset of the large Australian database was used for this study, which followed a "before-after" design.[8] Members of the "before" group (n = 12 851), aged 25 to 54, were interviewed in Sydney and Melbourne over a year starting in mid-

1982. Members of the "after" group (n = 11 609), aged 30 to 59 to control for a possible birth cohort effect, were interviewed 5 years later. The sampling method for the Australian study has been described elsewhere.[6–8] Smokers were defined as those who said they smoked tobacco products. In two separate subsamples, self-reported smoking was validated with saliva analysis for cotinine.[9]

We divided subjects according to age in 1982/1983: 25 to 35, 35 to 44, and 45 to 54 years old. Level of education was categorized into four groups: up to 9 years of schooling, a 10-year certificate, a 12-year certificate, and some college education.

We used the rate ratio to measure changes in smoking behavior because this method controls for differences in initial smoking prevalence between groups by expressing the "after" prevalence as a percentage of the "before" prevalence. The relative decline in prevalence is thus (100 − rate ratio)%. The Mantel-Haenszel method[10] was used to determine the age-adjusted rate ratio and its 95% confidence interval for both genders within each city. We used multiplicative (rate ratio) models[11,12] to assess the probability of being a smoker as a function of age, year of interview, and level of education, and we calculated the probabilities separately for men and women in both Sydney and Melbourne. Backward elimination of terms in the saturated model was used to test the significance of interactions and main effects. In particular, a statistically significant ($P < .05$) interaction between level of education and year of interview would indicate that the rate of change in smoking prevalence between the two surveys differed across educational groups.

Results

The distributions of age and of educational level were similar for the 1982/1983 and 1987/1988 groups (Table 1), but adjustment for those variables was still necessary because of their strong association with smoking prevalence.

Tables 2 and 3 show smoking prevalence and rate ratios for men and women, respectively, indicating a clear gradient for smoking prevalence across educational levels: smoking prevalence in the least educated group is generally 70% greater than it is in the most educated group. The rate ratios show an overall de-

cline in prevalence as they are consistently below 100%. For both Sydney and Melbourne men and for Sydney women, the rate ratios for the four levels of education are not significantly different; i.e., after controlling for age, the relative decrease in smoking of the least educated group is not significantly different from that of the most educated group. The pattern differs, however, for Melbourne women, for whom there is a significant difference between the age-adjusted rate ratios of the four educational levels. The rate ratios vary from 96% (least educated group) to 77% (most educated group); the 23% decline in prevalence in the most educated group is the greatest seen among any group in either city, and the 5% to 9% declines among the other educational groups of Melbourne women are the lowest rates of decline of all groups studied.

Discussion

In Sydney and Melbourne, a significant decline in smoking prevalence occurred between the survey years 1982/1983 and 1987/1988.[7,8] This decline contrasts with the relatively stable smoking levels of the previous decade,[8,13] and the drop has been attributed to the mass media–led antismoking campaigns.[7,8] Despite the large sample sizes, we found no evidence that the gap in smoking prevalence between the educational groups increased over the study period in three of the four study groups. The exception occurred among Melbourne women, where only the higher educated showed a decline in smoking. The same group, Melbourne women, did not show any long-term decline in smoking clearly attributable to the campaign.[8]

These results are among the first reported examples of a health promotion–motivated behavioral change that did not lead to an increase in the gap between educational levels. They suggest that the much larger decreases in smoking prevalence seen among better-educated groups in previous studies may have been related to differences in exposure to motivational material rather than to differences in behavior-changing skills. To address the needs of smokers of all educational levels, the public health movement should conduct antismoking campaigns using the full powers of visual mass media. □

Acknowledgments

The data used in this study were collected as part of the evaluation for both the "Quit for Life" program conducted in Sydney and the Quit campaign conducted in Melbourne. We wish to thank Bev Higham of "Quit for Life" and the directorate of the drug offensive for their support and partial funding for the project. Additional funding for data collection came from the Anticancer Council of Victoria as part of their evaluation of the Melbourne Quit campaign.

Demographic and Socioeconomic Differences in Beliefs about the Health Effects of Smoking

Ross C. Brownson, PhD, Jeannette Jackson-Thompson, PhD, MSPH, Joan C. Wilkerson, BA, James R. Davis, PhD, Nancy W. Owens, MEd, and Edwin B. Fisher, Jr, PhD

ABSTRACT

To assess sociodemographic differences in beliefs about the health effects of cigarette smoking and passive smoke exposure, we recently surveyed 2092 adults in St. Louis and Kansas City, Mo. The percentages of respondents who knew that smoking causes lung cancer, emphysema, and heart disease were 76.7, 74.1, and 67.2, respectively. After multivariate adjustment, knowledge about smoking's health effects was generally lower among women, older respondents, those of lower education level, and current smokers. Blacks were generally less likely to appreciate the health effects of active smoking, but were more likely to acknowledge the health effects of passive smoking. (*Am J Public Health*. 1992;82:99–103)

Introduction

The harmful health effects of cigarette smoking are well documented. Cigarette smoking was first linked to lung cancer in 1950,[1] and in 1964 the US surgeon general found that smoking was causally associated with lung and laryngeal cancers and chronic bronchitis.[2] Cigarette smoking is now considered the leading avoidable cause of mortality in the United States, accounting for approximately 434 000 deaths in 1988.[3]

The health hazards of passive smoke exposure have only recently been established. Passive smoking is now regarded as a cause of lung cancer in healthy nonsmokers,[4,5] accounting for approximately 3800 lung cancer deaths per year in the United States.[3] In addition, the children of parents who smoke have a higher frequency of respiratory infections and decreased lung function as the lungs mature.[4,5]

Public knowledge and beliefs about the health risks of smoking and passive smoke exposure have increased substantially over the past several decades. For example, between 1964 and 1987, the percentage of adults who knew that smoking causes lung cancer increased from 66 to nearly 90.[6,7] It also appears that a majority of the population is aware of the health hazards of passive smoking. A nationwide study in 1986 found that 81% of respondents knew that passive smoke exposure was hazardous to nonsmokers' health.[8]

Despite considerable gains in public knowledge about smoking, substantial numbers of smokers are still unaware of or do not accept the health risks of smoking.[4] In addition, few studies have examined related issues such as knowledge of nicotine addiction, the health benefits of quitting, and passive smoking health issues. Even fewer studies have evaluated knowledge about smoking and passive smoking among high-risk groups such as minorities and persons of lower socioeconomic status.[9–11]

This paper presents information on knowledge and beliefs about cigarette smoking and passive smoke exposure that was collected in a recent survey of an urban adult population.

Methods

The present study was conducted to provide planning and evaluation data for a smoking prevention and cessation intervention in a high-risk, inner-city population. From March through September 1990, computer-assisted telephone interviews were conducted with 2092 adults 18 years of age and older. Study subjects were randomly selected from among residents of approximately 60 census tracts in St. Louis and Kansas City, Mo. Techniques for the sample selection and survey were based on the Behavioral Risk Factor Surveillance System.[12] A two-stage, random-digit dialing technique was used to collect data from residents of these lower-socioeconomic-status, predominantly Black neighborhoods. During the first stage, most nonworking and ineligible telephone numbers were eliminated. In the second stage, a respondent was identified from among all adult residents of the household.[12] The response rate among eligible households was high (93%). Table 1

Never smoker	1009	48.2
Former smoker	406	19.4
Current smoker	677	32.4

presents the distribution of the study population by selected factors.

The study questionnaire was a modified version of the Behavioral Risk Factor Surveillance System instrument.[12] (A copy of the questionnaire is available from the first author on request.) Tobacco-related questions focused on smoking history, knowledge and beliefs about the health effects of smoking and passive smoke exposure, and attitudes toward tobacco use and tobacco control policies. Questions on smoking history and knowledge about health effects of smoking were based on standardized questions from the American Lung Association,[13] the Adult Use of Tobacco Survey,[8] and National Cancer Institute-funded researchers.[14,15]

Initially, simple frequencies were calculated by sociodemographic grouping.[16,17] Also, logistic regression was used to calculate odds ratios (ORs) and 95% confidence intervals, while simultaneously adjusting for other independent variables.[18] Trends in proportions were also evaluated.[19,20]

Results

Table 2 presents respondent knowledge and beliefs about the health effects of cigarette smoking. The vast majority of respondents (88.4%) believed that smoking is harmful to health. Belief in harmful health effects was inversely related to age and positively correlated with education level ($P < .001$). Current smokers were significantly less likely than never smokers to acknowledge the health effects of smoking (OR = 0.5). The overall percentages of respondents who knew smoking causes specific diseases such as lung cancer, emphysema, and heart disease were 76.7, 74.1, and 67.2, respectively (not shown in a table). As with the general question regarding the harmful health outcomes of smoking, knowledge of smoking as a cause of these three diseases was generally lower among older respondents, women, less-educated subjects, and current smokers (Table 2).

Sociodemographic differences regarding beliefs about the addictive nature of cigarette smoking and the health benefits of quitting are shown in Table 3. The majority of respondents knew that cigarette smoking was physically addicting (88.6%), and that there are health benefits from quitting smoking (83.2%). After multivariate adjustment, respondents 55 years of age and older (OR = 0.6) and current smokers (OR = 0.7) were significantly less aware of the addictive nature of smoking. Less-educated respondents were less likely to acknowledge the health benefits of quitting.

Table 4 shows the distribution of the study population regarding beliefs about passive smoke exposure. A majority of respondents believed passive smoke exposure to be harmful to nonsmokers' health (78.2%), harmful to young children (87.2%), and annoying (65.5%). Results regarding health effects and annoyance of passive smoking were inversely correlated with age ($P < .001$). Blacks were more likely than Whites to agree that passive smoke exposure is harmful to young children's health (OR = 1.3) and to find passive smoke annoying (OR = 1.2). Current smokers were significantly less likely than never smokers to acknowledge the effects of passive smoking on nonsmokers' health (OR = 0.3) and children's health (OR = 0.2) and were less often annoyed by passive smoke (OR = 0.1).

Discussion

Since relatively few studies have described sociodemographic differences in beliefs about the health effects of smoking and passive smoke exposure, our results provide some useful insights. Although differences were not always statistically significant after multiple adjustment, we found knowledge about the health effects of smoking and passive smoking to be lower among older age groups, women, less-educated respondents, and current smokers. Racial differences were interesting in that Blacks were generally less likely to appreciate the health effects of active smoking but were more likely to acknowledge passive smoking's health effects.

The percentages of respondents in our study who knew that smoking causes lung cancer, emphysema, and heart disease were slightly lower than those found in two recent national studies.[7,8] For example, the American Lung Association[7] found that a majority of respondents knew smoking is a cause of lung cancer (87%) and emphysema (85%). The corresponding figures for our study were 77% and 74%, respectively. As in previous studies,[7,8] subjects in our study were most likely to recognize lung cancer as a consequence of smoking and least likely to recognize heart disease.

Numerous perspectives in behavioral science (e.g., the health belief model) assert that an individual needs to feel susceptible to a health risk prior to changing behavior.[4,21] Our data show that for both general health effects and specific disease threats, smokers are significantly less likely than nonsmokers or former smokers to acknowledge the harmful effects of smoking. For example, 33% of current smokers in our study, almost twice as many as among never smokers, were unaware that smoking is a cause of lung cancer. More striking, perhaps, are comparisons for heart disease. Smoking is the

cause of larger numbers of heart disease than lung cancer deaths,[3,4] yet almost 40% of current smokers, as opposed to 29% of former smokers, indicated a lack of awareness of this grave risk. This reaffirms that many smokers underestimate or deny the serious health risks of smoking.[4]

Although the 1988 surgeon general's report clearly determined that cigarette smoking is a potent addiction,[22] few data are available on public understanding of this addiction. A 1986 survey in Canada found that 76.5% of respondents believed cigarette smoking to be addicting.[23] Of the subjects we surveyed, 89% felt that cigarette smoking was addicting. Knowledge of this addiction was significantly lower among persons 55 years of age and older and among current smokers.

Understanding of the health effects of passive smoking was relatively high in our study. Overall, 78% of those surveyed indicated that passive smoke exposure was harmful to nonsmokers' health. This compares with 81% of those surveyed in two recent national studies.[8,24] The majority of respondents acknowledged the detrimental effects of passive smoke exposure on children. Among subgroups, knowledge was lower in older age groups, women, Whites, and former or current smokers. Most of those surveyed were annoyed by passive smoke exposure, as reported earlier.[25] Data on passive smoking annoyance affirm the declining social acceptability of smoking in public places. Nearly

[c]Each OR was adjusted by logistic regression for all other variables in the table.[18]
[d]Results for other racial/ethnic groups are not shown because of small numbers.

40% of the current smokers we surveyed were annoyed by others' cigarette smoke.

Our findings may not be entirely representative of the general population, since we surveyed a low-income population. Thirty percent of the respondents in our study had household incomes of less than $10 000 per year, which compares with 22% of the overall state population.[26] However, since low socioeconomic status is a strong predictor of smoking prevalence,[9] the need for additional research in low-income populations is apparent.

The current study demonstrates some important sociodemographic differences in knowledge and beliefs about the health effects of cigarette smoking and passive smoke exposure. The patterns that we identified should be considered when targeting public education and advocacy efforts to the segments of the population at highest risk for smoking and passive smoke exposure. □

Geographic and Gender Variations in Total Tobacco Use

Donald R. Shopland, Steve J. Niemcryk, PhD, and Katherine M. Marconi, PhD

ABSTRACT

This study is the first to provide complete information on prevalence rates by gender and geographic variation for each type of tobacco product used in the United States. Results indicate that, in nearly half of all states, total tobacco use in men exceeded 40% and, in four states, exceeded 50%. In women, only Nevada, Kentucky, and Michigan reported prevalence exceeding 33%. Results also indicate, however, that concurrent use of multiple tobacco forms is relatively rare.

Substantial regional variation in male total tobacco use was evident, with southern males exhibiting the highest prevalence rate (44.6%). As a result, this region represents a target group in special need of comprehensive and effective tobacco use interventions. (*Am J Public Health.* 1992;82:103–106)

Introduction

National surveys conducted since 1955 have systematically documented the major demographic and socioeconomic variables associated with tobacco use, especially cigarettes.[1–4] Considerably less attention has been paid to differences in prevalence by geographic location, and until 1985, no single national study existed that was capable of providing complete prevalence estimates for each type of tobacco product used (i.e., cigarettes, pipes, cigars, chewing tobacco, and snuff) within various geographic strata.

In September 1985, the Office on Smoking and Health, DHHS, added a brief series of questions on current tobacco use practices to the Current Population Survey (CPS). Owing to its large sample size and unique design, the September CPS is the only survey currently capable of producing reliable prevalence estimates for individual tobacco products by geographic location, including each of the 50 states and the District of Columbia.[5,6] The purpose of this analysis is to use the 1985 CPS to provide estimates of the prevalence of use of individual tobacco products, by gender, and of the use of at least one tobacco product for each region, division, and state.

Methods

The methodology of the CPS has been described in detail elsewhere.[7] Briefly, based on the 1980 census file and on a system of stratified random sampling, eligible households from each state and the District of Columbia were identified. For each eligible household, questionnaires were completed for each household member aged 16 or older (n = 114 342). Proxy respondents were used to provide data on approximately 45% of the sample.

For this analysis, only data from individuals aged 20 or older (n = 105 225) were used to reduce the potential problem of using proxy responses for younger age groups. Subjects who reported using tobacco in any form—cigarettes, cigars, pipes, snuff, or chewing tobacco—at the time of interview were classified as current users. Definitions used to determine tobacco use status in the CPS were identical to those used in the National Health Interview Survey (NHIS), as well as in other surveys conducted by various federal agencies.

Note. Percentages are based on the number of male and female subjects within the individual geographic catagories.
[a]Confidence intervals are calculated for the rate of use of at least one tobacco product. [b] Numbers in parentheses indicate the number males and females in the present analysis.

Results

Approximately one third (32.8%) of adults aged 20 and older used at least one type of tobacco product in 1985. Nearly 40% of all men reported using at least one form of tobacco in 1985 compared with 26.6% of all women. (Table 1). Use of multiple forms of tobacco, however, was relatively rare among males and was almost nonexistent among females.

Among males, the prevalence of using specific tobacco products varied substantially by region (Table 1), with the South reporting the highest overall prevalence of male tobacco users (44.6%) and the West reporting the lowest (34.4%). Within regions, however, the percentage of females who used at least one product was only slightly higher than the prevalence of cigarette smoking alone whereas among males this difference varied considerably.

The prevalence of any tobacco use for males and females by individual states is presented in Tables 2 and 3. Rates are arranged in quintiles in descending order of prevalence for at least one form of tobacco use. For men, 10 of the 11 states with the highest prevalence of any tobacco use were southern states, and 9 of those 10 states were among the states with the highest prevalence of cigarette use. In nearly half of all states, the prevalence among men of using one or more tobacco product reached or exceeded 40%, and 12 states exhibited rates greater than 45% (Table 2).

For females, in only six states was the prevalence of using any tobacco product greater than 3% over that of using cigarettes alone (Table 3), and all six states are in the South. These states were the exception, however, because the prevalence of any tobacco use among females in all other states was less than 2 percent higher than that for cigarette use.

Discussion

Consistent with previously published reports,[4-8] the findings from the present study indicate that few females used tobacco in forms other than cigarettes and that rates of cigarette smoking among females did not vary significantly by region. Thus, the observed regional variation in total tobacco use is attributed almost exclusively to the patterns of male tobacco use, which was not limited to cigarettes. Levels of tobacco use among males in the different geographic areas differed substantially for total tobacco use, cigarettes, snuff, and chewing tobacco, but not for cigars and pipes.

The South clearly dominated other regions of the country in both cigarette use and use of at least one tobacco product among males. Given the substantially higher rates among southern men for both cigarettes and total tobacco use, southern females were expected to predominate in the rankings as well. Yet females from the South reported rates of cigarette use that were not substantially different from rates among women across the country overall, and the 10 states with the highest rates of cigarette smoking for females were about equally represented across the four regions. The absence of elevated smoking rates among southern women may indicate that the more traditional social norms and values historically associated with the South may have exerted a gender-specific effect on personal behavior that discouraged smoking by women but not by men. This would be analogous to contemporary norms regarding the social unacceptability of smokeless tobacco use by women or, the declining degree of public acceptance for smoking in various public settings.[9]

Prevalence estimates derived from the CPS are somewhat lower than those reported in other national surveys.[4] For example, in the 1985 NHIS, cigarette prevalence for women was 28.0% compared with 26.5% in the CPS (age-adjusted); the corresponding rates for men were 33.2% and 32.9% for NHIS and CPS, respectively.[10] Any differences observed between the CPS and NHIS can be at least partially attributed to use of proxy respondents. Nevertheless, based on this analysis, we estimate that approximately 54 million adult Americans used some form of tobacco in 1985.

Differences between men and women over the past 25 years in the documented rate of change in the prevalence of cigarette smoking has prompted some investigators to predict that cigarette

[a]Crude rates. [b]Confidence intervals are computed for the rate of use of at least one tobacco product.

prevalence among women may exceed that among men by the middle of the 1990s.[1] Given the findings from this analysis, the high rate of total tobacco use by men also must be addressed. When all forms of tobacco use are considered, use of tobacco among males still far exceeds that among females. Moreover, certain regions of the country—particularly states in and around the South—will require more intensive efforts to curb smoking and tobacco use if the nation's health goals for the year 2000 are to be achieved.[1]

[a]Crude rates. [b]Confidence intervals are computed for the rate of use of at least one tobacco product. [c]These states were found to have slightly higher rates (less than a difference of 0.25%) of cigarette use than of use of one tobacco product. This finding, which was considered "impossible" by our definition of a person's "using at least one tobacco product," is attributed to the fact that individuals with missing data on one or more tobacco products were excluded from the estimates of using at least one tobacco product.

Handmade Cigarettes: It's the Tube That Counts

ABSTRACT

Thirty-one Canadian brands of fine-cut tobaccos for roll-your-own cigarettes (RYOs) were evaluated under standard conditions using mandated tube and filter combinations. Results indicate no evidence of a significant difference in the amounts of tar, nicotine, and carbon monoxide produced by the 31 brands. In addition, the data emphasize that it is primarily the tube and filter combination that determines delivery of toxic constituents. (*Am J Public Health.* 1992;82:107–109)

Introduction

There is strong evidence suggesting that many cigarette smokers, being addicted to nicotine, would rather pay a higher price than give up smoking.[1] In countries such as Canada, which has two different taxation rates for manufactured cigarettes and manufactured (fine-cut) tobacco, smokers have the added choice of a cheaper substitute: roll-your-own (RYO) cigarettes.

While most people's image of RYOs is derived from Hollywood westerns, the truth is different. RYOs are easy to make and, after the recent introduction of some new products in Canada, virtually indistinguishable from machine-manufactured cigarettes. RYOs are so popular in Canada that, by the end of 1989, Canadian RYO sales accounted for approximately 14% of the cigarette market.[2]

As smokers of manufactured cigarettes have known for years, cigarettes produce tar and nicotine in measurable and consistent quantities.[1,3,4] Although the quantities measured will vary depending on how the cigarette is smoked,[1,3] smokers are very much aware of these toxic constituents.[1,3,4]

The situation for RYO tobaccos is different. Until recently, there was no information about levels of any toxic constituents on packages of RYO tobaccos. As a result, significant numbers of smokers have not had access to important information about the toxic constituents in the products they consume. Although some information is available, it is primarily in the scientific literature, and thus it is virtually inaccessible to the average smoker.[5]

To rectify this situation, one provision of the Canadian Tobacco Products Control Act, implemented in January 1989, requires manufacturers of cigarette tobaccos for RYOs to measure and report tar, nicotine, and carbon monoxide (CO) yields.[6] The Tobacco Products Control Regulations (TPCR) describe the standard methods to be used.[7]

By October 31, 1989, tar, nicotine, and CO values began appearing on all packages of RYO tobaccos sold in Canada. To determine how the choice of filter and tube combination might affect yields, the Health Protection Branch of Health and Welfare Canada commissioned a study to evaluate differences in the toxic constituent yields of 31 leading Canadian brands of RYO tobacco using the mandated tube and of 17 commercially available, nonmandated filter and tube combinations. All were filled with 900 mg of a homogeneous tobacco blend.

Methods and Apparatus

RYO tobaccos were purchased at either the wholesale or the retail levels in Toronto and Montreal during December 1989. The standard homogeneous tobacco blend was donated by Imperial Tobacco Limited.

Mandated tubes[7] were obtained directly from RJR-MacDonald Inc. of Montreal. Nonmandated tubes (in the 17 commercial brands) were purchased from a wholesaler in Kitchener, Ontario, Canada.

RYOs were prepared, smoked, and analyzed according to the TPCR[7] as amended on July 13, 1989. Smoking parameters included puff volume of 35 ± 0.2 mL; puff frequency of one puff every 60 ± 1 second; puff duration of 2 ± 0.2 second, and butt length of 23 mm.

Results

The mean analytical results (20 observations/brand) for tar, nicotine, and CO for the 31 brands of cigarette tobaccos tested using standard conditions are presented in Table 1. The overall means in milligrams per cigarette are 15.47 (standard deviation [SD] ± 0.41) for tar, 1.14 SD ± 0.09) for nicotine, and 17.69 (SD ± 0.56) for CO. The ranges in milligrams per cigarette are 14.64 to 16.29 for tar, 0.96 to 1.44 for nicotine, and 16.53 to 18.79 for CO. Statistical analyses of these results using Scheffe's

Note. KS = king size; RS = regular size; FT = filter tip.

Multiple Range Test did not provide any evidence for a difference in tar yields.

Table 2 presents analytical results for 17 filter and tube combinations using a standard blend of RYO tobacco. Mean values in milligrams per cigarette range from 7.93 to 21.04 for tar, 0.67 to 1.5 for nicotine, and 7.33 to 20.49 for CO. Within brand families such as Export, Players, and Rothmans, the delivery of tar decreased by about 50% between the "regular" tube and the lowest "ultra light" or "extra light" tube. The decrease in tar delivery between the regular and next lowest light tubes, however, is not as dramatic. In fact, in the case of Export and Export Light, the tar delivery increases although the difference may not be statistically significant.

Discussion

Cigarettes are composed of three major components: tobacco, filters, and the papers used in wrapping the tobacco and filter.[4] Cigarette manufacturers are able to adjust the tar, nicotine, and CO deliveries by manipulating any or all of these components.[3,4] Most often this involves using porous papers and ventilated filters, which dilute the mainstream smoke and thereby reduce the yields of toxic constituents.[3] The TPCR, in mandating a method for testing RYO tobaccos, have ensured that all brands are evaluated on a comparable basis with tobacco as the only variable.

Not surprisingly, there seems to be no substantial differences in RYO tobaccos marketed under the 31 brand names listed in Table 1. Virtually all of the tobacco used by Canadian manufacturers is domestically grown and flue cured, and approximately 89% of the flue-cured tobacco is grown in Ontario.[8] In addition, manufacturers claim that most of their cigarettes are additive free.[9] It is reasonable to conclude, therefore, that there should be no major differences in the standard yields.

Depending on the choice of tube, a smoker can vary tar delivery by approximately 60%. The tubes, however, are sold either separately or in combination with the corresponding tobacco. There is strong evidence that smokers and nonsmokers alike believe that low-yield cigarettes actually do produce lower concentrations of toxic materials.[1,3,10] Although no comparable evidence exists for consumer opinions concerning RYO tobaccos, it is reasonable to assume that users of these products may have a similar impression. Therefore, smokers may be buying low-yield RYO tobaccos in the mistaken belief that it is the tobacco that controls the yields of toxic constituents. But, as the results of this work indicate, it is the tube and filter combination, not the tobacco, that controls the delivery of toxic constituents to smokers. Thus, to achieve the low-yield effect, smokers should be advised to make their choices based on the tube and filter combinations rather than on the tobacco. □

Improvement in Intergenerational Health

ABSTRACT

Differences in health status between subjects, their parents, and their children were analyzed in 2206 subjects who had attended the University of Pennsylvania during the 1939 to 1940 school year. Subjects compared their overall health status at the average age of 70 with that of their same-sex parent at the same age and with that of their same-sex child at the approximate average age of 45, providing reasons for reported differences. Thus, health status in family members of the same sex at the same age in 1988 was compared with that in approximately 1963. Subject health was strikingly improved compared with that of their parents a generation earlier, with 58% reporting their health to be better or much better, and only 9% reporting it to be worse or much worse ($P < .001$). The major reasons for the difference were decreased prevalence of chronic conditions and healthier life-styles. The same results were observed in a community-based population of 327 subjects and, even more strikingly, in a group of 422 aging long-distance runners. These observations suggest substantial improvement in senior health status over the past quarter century in selected populations, and they contrast with equivocal changes that have been noted with traditional serial survey techniques. (*Am J Public Health.* 1991;81:109–112)

Introduction

Has the health of seniors improved over recent years? This controversial question[1–9] is of obvious importance to health policy. Intuitively, it seems that age-specific health status must be improving due to medical advances, decreases in some health risk behaviors, and improvement in mortality rates. But reliable data in this regard are notably lacking, and many studies suggest negative trends.[1] Disability has reportedly increased,[2–5] and prevalence may have increased for heart disease, hypertension, and arthritis.[3,6] Although global health measures remain stable,[1,7,8] death certificate studies show a growing number of listed causes.[9] However, there also has been greater disease ascertainment.[1] Public attitudes may now tolerate lesser degrees of disability, the "paradox of health."[10] There also have been changes in diagnostic standards, hospital admission standards, nursing home beds, and disability reimbursement. Thus, it is not surprising that there is controversy. We present a new analytic approach: we directly compare subject health with parent health.

Methods

We are studying, longitudinally, 2451 subjects who had attended the University of Pennsylvania during the 1939 to 1940 school year to identify risk factors for osteoarthritis.[11,12] Subject age averaged 69.7 years, 70% of subjects were male, and subject education level averaged 17.5 years. It may be of interest that 37% were former smokers but only 2.6% were current smokers.

In 1988 we asked the following questions:

1. How does your *present health* compare with that of your parent of the same sex when he or she was *your present age?* What are the major differences?
2. How does the *present health* of your oldest child of your sex compare with your health when you were *the same age?* What are the major differences?

Thus, we queried subjects for intergenerational health differences between themselves and both their parent at an average age of 70 and their child at age 45, assuming a 25-year generation. We thus compared health status in 1988 with that in

approximately 1963. This intrafamily comparison controls for age, sex, and, in part, genetic and social factors.

We also studied two additional groups at similar ages: 422 long-time, long-distance runners from a 50-plus runners club and 317 community controls from the Lipid Research Clinic Study.[13–15]

Independent variables studied included sex, highest grade level, age, race, smoking history, family history of arthritis, disability index (0 to 3) using the Health Assessment Questionnaire (HAQ),[16–18] and global health as marked on a horizontal analog scale (0 to 100)[16,18] Dependent variables were subject health compared with that of both parent and child, analyzed by chi-square analysis. Subject characteristics are summarized in Table 1.

Results

Main results are shown in Figure 1. An overwhelming 58% of subjects reported that their health was better or much better than that of their parent compared with 9% reporting health that was worse or much worse ($P < .0001$). The mode was "much better." In contrast, when comparing their health with that of their same-sex child, 25% reported the child's health to be better or much better and 12% reported it to be worse or much worse ($P < .001$). Median and mode were "same."

Table 2 summarizes responses in subgroups characterized by sex, age, and educational level, with categories of better/much better and categories of worse/much worse collapsed. The same results obtained in every subgroup (all $P < .001$). Among the 50-plus runners club subjects, 82% reported better health than their parent ($P < .0001$), as did 66% among the community control population ($P < .001$). In neither of these populations were comparisons with child health statistically different.

Reported reasons for better health are grouped in Table 3. Presence of cardiac, respiratory, and other diseases in the parent accounted for approximately half of the responses. Greater exercise, life-style and diet factors, obesity, and smoking and drinking accounted for the remainder.

Discussion

Subjects reported marked health improvement compared with their parents. Results were confirmed in multiple subgroups and in two additional populations. The attributed reasons for improvement are consistent with decreases in cardiovascular disease and improvements in lifestyle between 1963 and 1988.

Are there intrinsic biases in this technique? Three general caveats apply. First, in cross-sectional studies there is selection bias (left-censoring) due to deaths prior to study date in the original cohort. Subjects thus may have better health than average. However, we did not analyze subjects outliving parents and thus in "much better" health; if we had, results would have been even more pronounced. Additionally, because of increased longevity, fewer subjects than parents should be left-censored by death. This potential bias, therefore, works against the observed results.

Second, results are based on self-report. There could be a general tendency to see personal health as better than it is. This potential bias cannot be excluded, but the neutral or negative responses to the "control" comparison with child health tend to make this less likely. The "paradox of health" suggests that individ-

ual responses might actually be more often pessimistic than optimistic.[10] Previous validation studies on these populations comparing reported to observed disability levels showed equal accuracy in exercising and sedentary groups.[3]

Third, subjects studied were educated and, generally, not underprivileged. Nevertheless, results were consistent across all groups analyzed, including a community-based group. Readers may confirm results simply by posing the same questions to themselves, their family, and their acquaintances.

The compression of morbidity (COM) hypothesis[19–21] holds that, if the average onset age of infirmity is delayed and if this delay is greater than increases in longevity, the amount of life spent infirm will decrease. Such a more "rectangular" course anticipates prolongation of the period of health, followed by a more precipitate decline in health prior to death. These circumstances indirectly support the COM hypothesis, which requires a decrease in age-specific morbidity rates. Adult life expectancy (from age 50) increased by about 3 years between 1963 and 1988.[22] The striking health improvement reported will probably have a greater effect on than this modest longevity increase, but direct comparison of morbidity and mortality trends is not possible from our data.

Nor can the cause of the improvement be established definitively. Life-style changes that were cited suggest a partial role of personal health risk reduction. The decreased frequency of chronic diseases that was cited may be due to prevention or to improved care. These results cannot be generalized to underprivileged populations that experience fewer changes in health risks or have inadequate access to care. However, results suggest that, at least in certain population segments, substantial improvements in senior health status have occurred over the past generation. □

The Effect of Legal Drinking Age on Fatal Injuries of Adolescents and Young Adults

ABSTRACT

This study examined the effect of legal drinking age (LDA) on fatal injuries in persons aged 15 to 24 years in the United States between 1979 and 1984. Effects on pre-LDA teens, adolescents targeted by LDA, initiation at LDA, and post-LDA drinking experience were assessed. A higher LDA was also associated with reduced death rates for motor vehicle drivers, pedestrians, unintentional injuries excluding motor vehicle injuries, and suicide. An initiation effect on homicides was identified. Reductions in injury deaths related to drinking experience were not found. In general, a higher LDA reduced deaths among adolescents and young adults for various categories of violent death. (*Am J Public Health.* 1992;82:112–115)

Introduction

While the effect of raising the legal drinking age (LDA) on reducing the involvement of young drivers in fatal motor vehicle crashes has been demonstrated,[1,2] the potential impact of this legislation on other alcohol-related violent deaths[3–16] has not been examined except in one state.[17] Therefore, this study investigates the relationship between LDA and all fatal injuries among adolescents and young adults.

The literature has suggested four possible effects of LDA:

1. *Legal Effect:* A high LDA reduces fatal injuries among adolescents targeted by the law.[2]
2. *Spillover Effect:* A low LDA increases fatal injuries among adolescents younger than the LDA through earlier access to alcohol from their older aged peers.[1,2]
3. *Initiation Effect:* An increase in fatal injuries in the year that access to alcohol becomes legal offsets the reductions of earlier years.[18,19]
4. *Experience Effect:* Reductions in fatal injuries occur as drinking experience increases. Fatal injuries decrease in the years following legal access.[18,19]

Methods

All 50 states and the District of Columbia were studied for the years 1979 through 1984. In each state and each year, LDA and injury death rates for persons 15 through 24 years of age were determined. Information on LDA was obtained from the Insurance Institute for Highway Safety (Table 1). Mortality data were col-

lected from the National Center for Health Statistics. Injury deaths (E800–999) were identified, and six categories of death defined on the basis of the *International Classification of Diseases* (9th version; ICD-9) E-code were examined: motor vehicle driver, motorcyclist, pedestrian, unintentional injury excluding motor vehicle, suicide, and homicide (Table 2). The 1980 census provided population data to compute death rates. Census figures were adjusted by extrapolation to arrive at denominator data for the years 1979 and 1981 through 1984 (e.g., persons who were 18 in 1980 were considered 19 in 1981).

For each of the six categories of injury, the data were aggregated into death rates per 100 000 population by calendar year, age, and LDA, thus forming a matrix of 240 rates (6 calendar years × 10 single years of age × 4 LDAs). Calendar year was added to control for temporal trends in injuries. Logistic regression was used for analysis. The following model was fitted to the data:

$$\text{Rate} = a + b_1(\text{CALYR}) + b_2(\text{AGE}) + b_3(\textit{SPILLOVER}) + b_4(\textit{LEGAL}) + b_5(\textit{INITIATION}) + b_6(\textit{EXPERIENCE})$$

where Rate = fatal injury rate, CALYR = calendar year, AGE = age of the fatally injured person, SPILLOVER = LDA − age, if age < LDA (else 0), LEGAL = 1 if drinking legal at age of death or else 0, INITIATION = 1 if LDA = age or else 0, and EXPERIENCE = age − LDA + 1, if age > LDA (else 0). For the variables calendar year and age, a system of indicator variables was constructed to allow for expected nonlinearities in the death rate over time and age.

The following hypotheses were tested. If a low legal drinking age increases injuries in adolescents younger than the legal minimum—the "spillover effect"—injury rates will decrease as the years before legal access increase. If a high drinking age reduces injuries only among adolescents targeted by the legislation—the "legal effect"—a low drinking age will be associated with a high injury death rate among those who can drink legally. If an "initiation effect" occurs, fatal injuries will increase more than expected in the year that drinking becomes legal. If injuries decrease in the years following legalization—the "experience effect"—injury rates will decrease as experience with alcohol increases beyond the year that drinking becomes legal.

TABLE 2—Injury Death Rates and Deaths by Cause, for Persons Aged 15–24 Years, United States, 1979–1984

Cause of Death	ICD-9E Code	Death[a] Rate	No. of Deaths
Motor vehicle driver	E810–E819 (.0) E822–E824 (.0)	13.48	33 650
Motorcyclist	E810–E819 (.2, .3) E822–E824 (.2, .3)	4.38	10 923
Pedestrian	E810–E819 (.7) E822–E824 (.7)	3.57	8903
Unintentional[b] injuries excluding motor vehicle	E800–E807 E820–E821 E825–E949	15.24	38 034
Suicide	E950–E959	12.24	30 542
Homicide	E960–E978	13.84	34 526
All injuries[c]	E800–E999	82.55	206 002

Note. ICD-9 = *International Classification of Diseases*, 9th revision. (.0) = motor vehicle driver; (.1) = motor vehicle passenger; (.2) = motorcycle driver; (.3) = motorcycle passenger; (.7) = pedestrian; and (.9) = unknown.
[a]Number of deaths per 100 000 persons.
[b]Includes causes of injury death (e.g., drowning, house fire, fall).
[c]Includes the above categories of injury death as well as Motor Vehicle Occupants, E810–E819 (.1, .9) and E822–E824, (.1, .9) and Undetermined, E980–989.

TABLE 3—Estimated Effects of Legal Drinking Age on Injury Death Rates among Younger Adolescents (Spillover), Targeted Adolescents (Legal), Year of Majority (Initiation), and Young Adults (Experience), Aged 15–24, 1979–1984[a]

	Spillover		Legal		Initiaiton		Experience	
Cause of Death	OR	95% CI	OR	95% CI	OR	95% CI	OR	95% CI
Motor vehicle driver	0.958[b]	(0.941,0.975)	1.062	(0.999,1.128)	1.009	(0.962,1.059)	1.051[b]	(1.037,1.065)
Motorcyclist	1.030	(0.997,1.063)	1.026	(0.921,1.141	1.080	(0.992,1.177)	0.989	(0.965,1.012)
Pedestrian	0.895[b]	(0.868,0.923)	0.933	(0.828,1.051)	1.013	(0.918,1.117)	1.124[b]	(1.094,1.154)
Unintentional injuries excluding motor vehicles	0.961[b]	(0.947,0.976)	0.982	(0.927,1.040)	0.947[b]	(0.903,0.994)	1.025[b]	(1.012,1.038)
Suicide	1.032[b]	(1.012,1.053)	1.097[b]	(1.028,1.17	1.004	(0.953,1.057)	0.985[b]	(0.972,0.998)
Homicide	1.010	(0.991,1.029)	0.994	(0.935,1.056)	1.051[b]	(1.001,1.104)	1.070[b]	(1.057,1.083)
All injuries	0.993[b]	(0.986,0.999)	1.039[b]	(1.013,1.064)	1.010	(0.990,1.031)	1.021[b]	(1.016,1.027)

Note. OR = odds ratio; CI = confidence interval.
[a]Controlling for age and calendar year.
[b]$P < .05$.

Results

In Table 3 (first column), the coefficients are in the predicted direction (less than one) and significant for the following three categories: motor vehicle driver (odds ratio [OR] = 0.958), pedestrian (OR = 0.895), and unintentional injuries excluding motor vehicle (OR = 0.961). Yearly reductions in deaths of 4.2%, 10.5%, and 3.9%, respectively, are seen. While the coefficients are not in the predicted direction for three categories of fatal injury, only one, suicide, has a 95% confidence interval greater than one. For all injuries combined (OR = 0.993), a reduction in deaths of 0.7% is observed for each year that the legal drinking age is delayed.

In the second column, the coefficients are in the predicted direction (greater than one) for three categories of fatal injury: motor vehicle driver, motorcyclist, and suicide. However, only suicide (OR = 1.097) is significant. This coefficient suggests that among persons of a given age who can drink legally, the suicide rate is 9.7% greater than among persons of the same age who cannot drink legally, controlling for the other effects. For all injuries combined (OR = 1.039), a 3.9% increase in death rate is observed among persons of a given age who can drink legally.

In the third column, while the coefficients are in the predicted direction (greater than one) for five categories of fatal injury, only one, homicide (OR = 1.051), is significant. This coefficient suggests a 5% increase in homicides in the year that access to alcohol becomes legal. For unintentional injuries excluding motor vehicles (OR = 0.947), the coefficient indicates 5% fewer injuries than expected in the first year of legal drinking.

In the fourth column, the coefficients are opposite to the predicted direction (less than one) and significant for motor vehicle driver (OR = 1.051), pedestrian (OR = 1.124), unintentional injuries excluding motor vehicle (OR = 1.025), and homicide (OR = 1.070). The coefficient is in the predicted direction for suicide (OR = 0.985). For all injuries combined (OR = 1.021), a death-rate increase of 2.1% per year post-LDA was found.

Discussion

While the effect of LDA on fatal injuries varies among categories and age groups, the results of this study suggest that the net benefit of a drinking age of 21 is found not only among motor vehicle drivers, but among other categories of violent death as well. The findings indicate that raising the LDA may have three effects: delaying legal access to alcohol among pre-LDA adolescents, preventing traumatic deaths that occur with legal access, and delaying the onset of heavy drinking and associated fatal injuries that can occur with experience.

The results of this study are consistent with the findings of earlier research on LDA and driver fatalities in which alcohol was actually measured.[20] Furthermore, the LDA during the period studied was not related to the percentage of the population residing in metropolitan areas among the states, a potential confounding factor. However, the results would be more definitive if blood alcohol concentrations had been available for all categories of traumatic death. Universal measurement and reporting of blood alcohol in the fatally injured by age would enhance the evaluation of this and other alcohol countermeasures. □

Evaluating the Treatment of Sexually Transmitted Diseases at an Urban Public Hospital Outpatient Clinic

Paul G. Shekelle, MD, MPH, and Jacqueline Kosecoff, PhD

ABSTRACT

Sexually transmitted diseases occur disproportionately among the poor, are often treated in public hospitals and clinics, and have not been subjected to quality-of-care evaluation. We designed a medical record abstraction system using well-established, specific process-of-care criteria drawn from the medical literature and experts and grouped into three levels of quality: excellent, adequate, and minimal. One hundred seventy-six consecutive patients were identified from the clinic logbook and their medical records abstracted. Deficiencies in history taking, physical examination, laboratory testing, treatment, and public health reporting were identified. (*Am J Public Health.* 1992;82:115–117)

Introduction

Gonorrheal urethritis, nongonorrheal urethritis, and pelvic inflammatory disease are among the most commonly occurring sexually transmitted diseases. Appropriate treatment is curative, while lack of appropriate treatment can lead to serious implications. Sexually transmitted diseases occur disproportionately among the poor and underinsured,[1] who are more likely to receive care at a public hospital or a health department clinic. It is important to understand the quality of care delivered at these institutions. Therefore, we undertook an evaluation of the treatment of sexually transmitted diseases at one urban public hospital clinic.

Methods

The study hospital is a county-run facility in the Los Angeles metropolitan area that serves a poor, predominantly Hispanic population. The hospital's medical walk-in clinic sees adult patients with nonemergent problems and is staffed by full-time and part-time physicians and by medical residents. The nursing staff is bilingual. Physicians do not use disease-specific forms to record clinical information. Virtually all patients with sexually transmitted diseases presenting Monday through Friday are seen in this clinic.

We designed a medical record abstraction system to measure the quality of the process of care given to patients diagnosed with gonorrhea, nongonorrheal urethritis, and pelvic inflammatory disease. In order to develop explicit process-of-care criteria, we examined recommendations from the Centers for Disease Control, the Los Angeles County Public Health Department, and the scientific literature, and we also talked with experts. The final set of criteria was approved by the clinic director and the physician in charge of quality assurance for the treatment of sexually transmitted diseases. The criteria were grouped into three levels of quality: excellent, adequate, and minimal (Table 1).

Patients presenting to the clinic from November 1987 through February 1988 were eligible for the study. Patients who had a physician-recorded diagnosis that was compatible with one of the study diseases were included. One hundred seventy-six patients for whom the medical record was available were identified, and their medical records were abstracted. The physician-recorded history and physical, progress notes, physician orders, nursing notes, and laboratory reports were reviewed. Analytic methods included frequency tables and *t* tests.

At the time of the study the authors were with the UCLA Division of General Internal Medicine, Department of Medicine, and the UCLA Department of Health Services, School of Public Health. Dr. Kosecoff is also with Value Health Sciences, Santa Monica, Calif.

Physical examination	5
Gonorrheal culture ordered	23
Pregnancy test (when indicated)	9
Approved treatment	22
Follow-up referral made	8

[a]Some records failed for more than one reason.

Results

Patient Characteristics

Sixty-nine percent of the 176 patients were males and 78% were age 30 or younger. One hundred fifty-eight (90%) of the patients presented because they were symptomatic; the remainder were asymptomatic patients with a known exposure. Of medical records that contained information about sexual contacts in the previous 30 days, 9 records (19%) indicated that the patient denied any recent sexual encounter, 33 records (69%) indicated that the patient had one partner, 4 records (8%) indicated two partners, and 2 records (4%) indicated three partners.

Compliance with Quality-of-Care Criteria

The frequency with which specific process-of-care items were recorded is shown in Table 1. For example, 100% of the records had documentation of the presence or absence of symptoms, 2% had documentation of the physician having asked about nongenital exposure site, 35% had documentation of the last sexual contact, and 58% had documentation of the patient's last sexual partner.

Two records (1%) met the criteria for excellent quality, 19 records (11%) met the criteria for adequate quality (but not excellent quality), and 106 records (60%) met the criteria for minimal quality (but not excellent or adequate quality). In total, 49 records (28%) failed to meet the minimal-quality criteria. The reasons for failure to meet the minimal level of quality are shown in Table 2. In addition, patients with nongonorrheal urethritis were more likely to receive less-than-minimal-quality care than were those with gonorrhea (41% and 19%; $P < .05$).

Discussion

Our study found clinically meaningful deficiencies in the treatment of sexually transmitted diseases at one urban public hospital. These deficiencies included underuse of gram stains, chlamydia assays, and blood syphilis serology testing; inadequate history taking, patient risk assessment, physical examination, and patient follow-up; improper treatment; and poor public health reporting.

Some of these deficiencies may reflect local problems, for instance, a 2-hour turnaround time to receive results of a gram stain and a policy that a patient should call to schedule a return appointment rather than be given a follow-up appointment before leaving the clinic. Chlamydia assays, on the other hand, may have been underused because physicians doubted the worth of this test. The low rate of positive results (13% of chlamydia assays demonstrated positive results in this study, which is less than half the 31% rate of positive gonorrheal cultures) was known to the clinic staff. In addition, national recommendations for proper ther-

apy for all patients with gonorrhea include doxycycline for possible coexistent chlamydia. Removing the chlamydia test criterion from the definition of excellent quality increases membership in this category from two to six patients. Finally, the low level of public health reporting and the underuse of syphilis serology testing is particularly important since contact tracing is crucial to prevent further spread of disease.[2] In the study population, 3% of the syphilis serology tests were positive.

A goal of public health policy is to encourage poor patients with sexually transmitted diseases to seek care. We have shown that when such patients did seek care at one outpatient clinic, significant deficiencies existed in the documentation of well-established process-of-care criteria. If our results are generalizable, then the goals of public health policy should be broadened to include improving the quality of care provided to patients with sexually transmitted diseases. □

Acknowledgments

This paper was presented in part at the joint session of the national meetings of the Society of General Internal Medicine and the American Federation for Clinical Research in Seattle, May 1991.

The authors thank Dr. Satwant Sidhu, MD, MSPH, and Dr. Pramod Gan, MD, for their assistance in defining the process-of-care criteria used in this study and Dr. Robert Brook, MD, ScD, for his valuable critique of the manuscript.

Surveillance of Sentinel Occupational Mortality in the District of Columbia: 1980 to 1987

Ann Cottrell, BA, Eugene Schwartz, MD, MPH, Rosemary Sokas, MD, MOH, Vincent Kofie, PhD, and Laura Welch, MD

ABSTRACT

Epidemiological surveillance of sentinel occupationally related deaths commonly relies on computerized analyses of mortality data obtained from vital statistics records. A computer search of death records in the District of Columbia for the period 1980 to 1987 identified 15 cases that noted asbestosis, silicosis, coal worker's pneumoconiosis, or primary cancer of the pleura/mesothelioma as the underlying cause of death. A manual review of the death certificates for the same period identified three times as many cases (n = 48) with any mention of these conditions. Problems with performing surveillance of these events using death certificates include the lack of sufficient information to identify mesotheliomas and the failure to code and computerize all contributing causes of death. (*Am J Public Health*. 1991;82:117–119)

Introduction

Occupational disease surveillance can be used to plan, implement, and evaluate public health interventions that are designed to prevent or control work-related morbidity and mortality. The simplest surveillance systems have been based on the concept of "sentinel health events," as described by Rutstein et al. and others.[1,2]

An ongoing surveillance system may serve to (1) identify occupational or community cohorts that may benefit from medical screening, counseling, or epidemiological follow-up; (2) identify industries, particular companies, or neighborhoods that may require industrial hygiene evaluation, engineering controls, or hazardous waste remediation; (3) measure the impact of selected work-related exposures on the mortality of a population; and (4) provide an evaluation tool to determine the impact of regulatory measures.[1] As of 1988, 40 states and the District of Columbia have initiated efforts to code the decedent's industry and occupation on death certificates.[3]

We report the results of a pilot population-based surveillance project performed in the Washington, DC metropolitan area, which includes the nation's capital and surrounding areas of Maryland and Virginia. The estimated population of this metropolitan area is 3.25 million persons, 28% of whom are Black.[4] The District itself is home to 639 000 residents, 70% of whom are Black and 19% of whom live below the poverty level. The entire metropolitan area includes 1.5 million workers, 36% of whom work in the District,[5] while the District population itself includes 295 100 workers, 70% of whom work within its borders.[5]

Methods

A manual review of all death certificates maintained by the District of Columbia's Division of Vital Statistics and Research for the period 1980 to 1987

TABLE 1—Sentinel Occupationally Related Deaths by Race, Sex, and Age at Death: District of Columbia, 1980–1987 Automated and Manual Search of Death Records[a]

Cause of Death	Race-Sex Group	Number of Cases	Mean Age, y	Range, y
Mesothelioma	Black males	11	67	
	White males	11	67	
	Black females	3	73	
	White females	9	63	
		Group total = 34 (9)	66	34–88
Asbestosis	Black males	3	62	
	White females	1	84	
		Group total = 4 (1)	69	53–84
Silicosis	Black males	3	59	
	White males	3	80	
		Group total = 6 (3)	67	40–80
Anthracosis	Black males	1	71	
	White males	3	85	
		Group total = 4 (2)	82	71–100
Total Number		48 (15)	68	34–100

[a]Numbers in parentheses denote the number of cases identified by automated search.

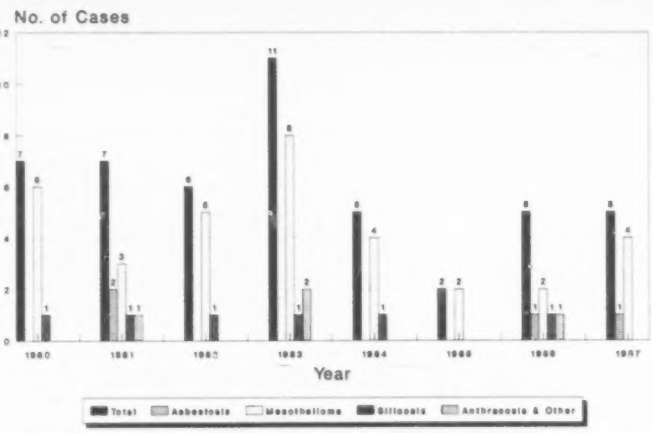

FIGURE 1—Trends in selected sentinel deaths in the District of Columbia, 1980–1987.

(n = 70 537) was performed to identify certificates that had any mention of silicosis,[3] asbestosis,[1] coal worker's pneumoconiosis,[2] or mesothelioma or cancer of the pleura.[9] These four health events that were occupationally related (SHE-Os) (Sentinel Health Event—Occupational) were considered to be almost certainly attributed to occupational or environmental exposure. Additionally, a computerized search using codes from the *International Classification of Diseases,* 9th revision *(ICD-9),*[6] was made for all certificates on which the underlying cause of death was listed as *ICD-9* 163.9 (cancer of the pleura), 500 (coal worker's pneumoconiosis), 501 (asbestosis), 502 (silicosis), or 505 (pneumoconiosis—unspecified). Abstracted data included the decedent's age, sex, race, cause of death, usual place of residence, and usual occupation. Statistical testing of mean ages at death for various race and sex groupings was performed using the *t* test.

Results

The manual search identified 48 SHE-Os, with an average age at death of 68 years (range 34 to 100 years) (Table 1). Males accounted for 35 of the deaths (73%); females accounted for 13 of the deaths (27%), with an average age at death of 69 and 67 years respectively. When delineated by race and sex, Black males accounted for 18 of the deaths (38%), with an average age at death of 65 years. Seventeen deaths (35%) occurred among White males, with an average age at death of 72 years ($t = 1.65$, $P = 0.11$).

Figure 1 describes the number of sentinel deaths that occurred each year, delineated by cause of death. Mesothelioma was recorded on 34 death certificates, with an average age at death of 66 years (range 34 to 88). The occurrence of mesothelioma deaths fluctuated during the period, peaking in 1983. Five of the occupations listed on these death certificates were in the construction trades. Other occupational statements (e.g., housewife, cab driver) may indicate exposure earlier in the decedent's career, including military service, summer or part-time jobs, "carry-home" exposure, or environmental exposure. Two mesothelioma deaths occurred among barbers.

Asbestosis was listed as the cause of death on four death certificates, and silicosis was recorded on six. Five of the occupations listed on these death certificates were in either construction or mining. Anthracosis, or coal worker's pneumoconiosis, was recorded as the cause of death on four death certificates. Only one of the decedents was noted to be a miner.

The computerized search using the *ICD-9* codes listed above identified 15 deaths for the period 1980 to 1987. This number was substantially fewer than the 48 found in the manual search for the same period.

Discussion

Death certificates offer a readily accessible uniform data source for surveillance of occupationally related diseases. The limitations of death certificates are well known and include misclassification

of cause-of-death data as well as often sketchy or incomplete occupational history statements.[7,8] The usefulness of death records is further limited when only a singular underlying cause of death is coded and computerized. The lack of access to computerized multiple cause-of-death files precludes the ability of automated searches to identify cases in which sentinel occupationally related conditions may have been a contributing cause of death. In this study, the computerized review of death certificates coded with a singular underlying cause of death missed over two thirds of the SHE-Os identified by a manual search that considered all listed contributing causes of death.

In addition, conditions such as intrathoracic mesotheliomas are often difficult to identify through death certificates because they are not coded with sufficient morphological information to delineate them from lung cancers or cancers of the pleura. Peritoneal mesotheliomas are harder to identify through death certificates because they may be coded as carcinomatosis, disseminated cancer, or other nonspecific malignancies.[9] Finally, the method by which certifiers complete death certificates compounds the difficulty in identifying occupationally related deaths.[7,10]

The actual number of occupationally caused deaths is likely to be much higher than even that determined by the manual review. We limited our analysis to four sentinel causes of death that are exclusively occupational or environmental in origin. We did not include deaths due to other sentinel occupationally related cancers, such as lung cancer, bladder cancer, oropharyngeal cancer, gastrointestinal cancer, and leukemia, for which nonoccupational contributing factors may predominate. For example, estimates based on industrially exposed cohorts suggest that, for every mesothelioma death, there may be many additional asbestosis cases and asbestos-related lung cancer deaths.[11,12]

Several interesting points may be raised concerning the distribution of work-related deaths in the metropolitan Washington area. First, Blacks accounted for 44% of the deaths while accounting for only 24% of the work force in the metropolitan area and 36% of the work force in the District.[5] Also, the average age at death for Black males tended to be lower than that of White males, suggesting that Blacks in the Washington metropolitan area experience increased exposure in the workplace, face decreased access to health care once symptoms arise, or have a disproportionate number in occupations with the potential for exposure to occupational hazards.

Second, women accounted for more than 25% of all asbestos-related deaths, including one of the four asbestosis deaths. These points are of particular concern, given that death certificate coding is less accurate for minorities than for Whites[13] and that less attention is paid to obtaining occupational histories from female patients than from male patients.[14]

The third finding of interest is that construction workers represented 15% of all SHE-Os while representing only about 8% of the metropolitan area work force. Nationwide, the construction industry ranks third in the rate of work-related fatalities, surpassed by only mining and agriculture. Despite potential risks from health and safety hazards that are commonly encountered in the building and construction trades, the industry remains poorly regulated by the Occupational Safety and Health Administration and is often exempt from many federal standards.

The Washington metropolitan area work force has traditionally been considered "nonindustrial" because of the large proportion of governmental and office workers; hence, it has been deemed free from industrially related diseases. The findings of this pilot project suggest that work-related diseases do occur in areas with a relative absence of what is generally considered to be "heavy industry." Further, these data suggest the need for increased prevention and control efforts, particularly among the construction trades in the District of Columbia metropolitan area. □

Maternal Recall Error of Child Vaccination Status in a Developing Nation

Joseph J. Valadez, PhD, SD, and Leisa H. Weld, PhD

ABSTRACT

In the absence of vaccination card data, Expanded Program on Immunization (EPI) managers sometimes ask mothers for their children's vaccination histories. The magnitude of maternal recall error and its potential impact on public health policy has not been investigated. In this study of 1171 Costa Rican mothers, we compare mothers' recall with vaccination card data for their children younger than 3 years. Analyses of vaccination coverage distributions constructed with recall and vaccination-card data show that recall can be used to estimate population coverage. Although the two data sources are correlated (r = .71), the magnitude of their difference can affect the identification of the vaccination status of an individual child. Maternal recall error was greater than two doses 14% of the time. This error is negatively correlated with the number of doses recorded on the vaccination card (r = −.61) and is weakly correlated with the child's age (r = −.35). Mothers tended to remember accurately the vaccination status of children younger than 6 months, but with older children, the larger the number of doses actually received, the more the mother underestimated the number of doses. No other variables explained recall error. Therefore, reliance on maternal recall could lead to revaccinating children who are already protected, leaving at risk those most vulnerable to vaccine-preventable diseases. (*Am J Public Health.* 1991;82:120–123)

Introduction

This paper investigates the validity of mother's recall of a child's vaccination status. Vaccination cards are used as the accurate count of vaccinations to determine the direction and magnitude of maternal recall error. Previous research carried out on vaccination recall focused on American parents remembering their own vaccinations, rather than those of their children.[1] In this paper we recommend against using mother's recall for EPI monitoring and point out the importance of workable vaccination card programs.

Methods

During early 1987, a representative sample of 1680 households with children younger than 3 years was taken in Costa Rica in order to measure health services coverage.[2] Trained interviewers used a pretested survey instrument to collect data. Costa Rica's successful vaccination card policy made feasible the use of these data for a comparison between recall and recorded data.

One child younger than 3 years was randomly selected from the household. The mother was asked to remember the number of doses of BCG, DPT, polio, and measles vaccine that child had received. (The interviewer used body sites and local names for drugs.) Afterward, the vaccination card was requested and vaccination dates were recorded. Up to 11 vaccinations were included: 1 BCG, 4 DPT, 4 polio, and 2 measles.

Recall error was measured as the difference between the number of remembered vaccinations and the number of recorded vaccinations. Positive numbers indicated overestimation, which places children at risk by resulting in community health workers' failing to vaccinate children who still require additional doses. Underestimates result in the waste of resources by vaccinating children with unnecessary doses.

A total of 509 mothers were excluded from the study because they had lost the vaccination card, vaccination dates for any dose were illegible or missing, or the mother refused to try to remember a child's status for any vaccine. Few differences were shown by t tests in which the 1171 included mothers and the 118 excluded mothers with recall data were compared on various demographic variables.

Children who had never had a vaccination card were judged to have never been vaccinated, since Ministry of Health norms require a child to have or be given a vaccination card any time a vaccination is given.

Results

Vaccination Distributions

Distributions of the number of doses from the vaccination cards and from maternal recall are similar (Spearman's r = .65; see Figure 1). This suggests that in the absence of vaccination cards, maternal recall can be used as a valid estimate of coverage of the EPI program in Costa Rica. Both sources of data indicate a successful program. A conclusion of policymakers in this circumstance could be to continue the existing EPI program. However, the important public health question remains: Can maternal recall be used to identify an individual child at risk for vaccine-preventable disease?

Child Vaccination Status

The two data sources are correlated on an individual level (Spearman's r = .71) and the average difference is small, but large differences occur for some children (Table 1). Fourteen percent of the mothers mis-estimated by three or more doses. Thus, although maternal recall can be a

At the time of this study, the authors were with the Harvard Institute for International Development.

valid estimate of coverage, it should not be used to determine an individual child's vaccination status.

Spearman's correlations between maternal recall error and potential explanatory variables are given in Table 2. Number of doses on the vaccination card and the child's age showed large negative correlations with recall error (Figures 2 and 3). The correlation with age is primarily an artifact, because mothers with very young children who received few doses cannot underestimate the number of doses. The negative correlation between recall error and actual doses has important implications. It suggests that mothers whose children are most at risk for vaccine-preventable diseases tend to overestimate their children's vaccinations. Mothers whose children are the least vulnerable tend to exhibit conservative preventive behavior by underestimating their children's coverage.

Further analyses show that the range of recall errors decreases as the number of contacts with community health workers increases (e.g., number of previous children, number of persons living in the household; see Figure 4). However, there is no relationship between frequency of contact with community health workers and the likelihood of overestimates relative to underestimates of vaccination status, and so frequency of contact with the health system does not explain recall error. Other variables exhibited no significant effect.

Reanalysis of the data excluding the 62 mothers who claimed never to have had a vaccination card for their child did not change the results.

Type of Vaccination Regime

Cross-tabulations of maternal recall error against number of doses received are reported in Table 3 for each vaccination type. As with the overall results, the recall errors for measles, polio, and DPT vaccinations were inversely related to the actual number of vaccination doses. All of the mothers believed their children had received a BCG vaccination. Mothers whose children had received the vaccination remembered, but mothers whose children had not received it overestimated the number of doses.

TABLE 3—Maternal Recall Error by Number of Doses Received for Four Vaccination Regimes

Error	Number of Doses 4	3	2	1	0	Total
			DPT

Note. DPT $\chi^2 = 350.4$, $P < .001$; polio $\chi^2 = 385.4$, $P < .001$; measles $\chi^2 = 303.3$, $P < .001$; BCG $\chi^2 = 1000.9$, $P < .001$.

Discussion

A comparison of the number of vaccinations recorded in vaccination cards and the number recalled by mothers revealed important recall errors. Maternal recall error is correlated with vaccination frequency of the child. Whatever the actual number of doses, the recalled number of doses regresses toward the population average. The greater the frequency of contacts with the health system, the smaller the range of recall errors.

Although no data reported here explain the negative correlation, further research should consider memory problems and the effect of social norms regarding vaccinations.

The results reported above suggest that relying on maternal recall of a child's vaccination history may result in erroneous decisions about whether to vaccinate the child. Children who are most at risk for vaccine-preventable diseases could be the most likely to remain unvaccinated, owing to their mothers' overestimation of doses received. Children who are least vulnerable, because of prior vaccination, are most likely to receive redundant vaccinations, owing to their mothers' underestimation. Nonetheless, maternal recall rather than vaccination cards can be used to estimate coverage.

As a result, EPI policies using recall data may have limited construct validity and thus ought to support the development of national vaccination card programs. Such a program's cost could potentially be offset by the savings resulting from not vaccinating children who already are up to date in their vaccinations. □

Acknowledgments

The work upon which this study is based was performed under a subagreement with the Center for Human Services under its Cooperative Agreement NO. DPE-5920-00-A-5056-00 with the US Agency for International Development. We would like to express our gratitude to the coordinators of the field staff in Costa Rica, William Vargas Vargas and Silvia Boada Martinez; to the Director General of Health of Costa Rica at the time of the study, Dr Carlos Valerín; to the Country Representative for the Pan American Health Organization, Raul Pena; and to Dr James Heiby, the Program Officer of the PRICOR Project. The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 Fifteenth St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Mervyn Susser, DPH, Editor, *American Journal of Public Health,* 1015 Fifteenth St., NW, Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication and are not under consideration elsewhere.

Subscription price, individual, is $80/year US, $120/year international; **institutional,** $160/year US, $240/year international. Single copies $10 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 Fifteenth St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters.

Advertising Sales: Mary Beth Schultz, Advertising Manager, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact: Marilyn Butler, AJPH Reprints, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols. 1 to present are also available on microfilm.

Prevention: The Cost-effectiveness of the California Diabetes and Pregnancy Program

Richard M. Scheffler, PhD, Lisa B. Feuchtbaum, MPH, and Ciaran S. Phibbs, PhD

ABSTRACT

Background. The California Diabetes and Pregnancy Program is a new preventive approach to improving pregnancy outcomes through intensive diabetes management preconception and early in pregnancy.

Methods. Hospital charges and length of stay data were collected on 102 program enrollees and 218 control cases. Ninety program enrollees and 90 control cases were matched on mother's age, White's classification, and race. Regression models controlled for these variables in addition to MediCal status, birth weight, and enrollment in the program.

Results. Hospital charges were about 30% less for program participants and days in the hospital were roughly 25% less. The program effects were larger for women that enrolled before 8 weeks gestation. More serious diabetics were also found to have larger reductions in charges and days.

Conclusion. After adjusting for inflation and differences in charges across hospitals, $5.19 is saved for every dollar spent on the program. (*Am J Public Health.* 1992;82:168–175)

Introduction

The cost savings potential of many prevention programs may not be realized for years, making these programs unattractive investments for health policy decision makers.[1,2] Fortunately, many studies of the cost savings potential of prenatal prevention programs need only look at the immediate future (i.e., 1-year care) to assess the cost effectiveness of the intervention. These studies have generally focused on the benefits of prenatal care or the prevention of low birth weight. Importantly, in the past 10 years there has been increasing recognition that the infant and maternal complications associated with diabetes in pregnancy can be prevented.[3–7] This paper provides the first cost-effectiveness analysis of a new and widely accepted prenatal prevention program, the California Diabetes and Pregnancy Program (CDAPP).

The CDAPP, also known as the "Sweet Success" program, focuses on improving maternal and infant perinatal outcomes in pregnancies complicated by diabetes. The program's multidisciplinary team approach to care emphasizes early recruitment of pre-pregnant (prior to conception, or "pre-conception") and pregnant women with diabetes. Once enrolled, the women receive comprehensive prenatal care, including nutrition, education, and support services that have been specifically developed to meet the needs of diabetic women during pregnancy. This management approach has been shown to reduce diabetes-related complications during pregnancy to the rate seen in the nondiabetic population.[8–10] This approach to care, which has been shown to be effective in improving birth weight in the nondiabetic population,[11] is particularly well suited for managing high-risk pregnancies.

Although maternal and infant mortality have been greatly reduced by advances in insulin therapy over the past 10 years, preexisting diabetes mellitus remains a significant risk to the unborn child. Congenital malformations still account for nearly 50% of the deaths among infants born to diabetic mothers today.[12] Serious malformations are three to four times more likely to occur among infants of diabetic women than among infants of nondiabetics,[13] and affect 6% to 9% of all diabetic pregnancies.[3] These malformations occur very early in pregnancy, at a time when the diabetic woman may not yet be aware that she is pregnant.[14] For these malformations to be prevented, it is critical that maximum diabetes control be maintained prior to pregnancy and in the early weeks of embryogenesis.[15]

It is still not clear what specific biological mechanism accounts for these malformations, but it is widely accepted that the congenital malformation rate is correlated with the degree of glycemic control during pregnancy.[7,16] Although the appropriate degree of control is still being de-

Richard M. Scheffler is with the Schools of Public Health and Public Policy and Lisa B. Feuchtbaum is a doctoral candidate with the School of Public Health, both at the University of California, Berkeley. Ciaran S. Phibbs was with the School of Public Health, Columbia University, New York, NY, at the time of this study, and is now with the Center for Health Care Evaluation, Veterans Administration Medical Center, Palo Alto, Calif.

Requests for reprints should be sent to Richard M. Scheffler, PhD, School of Public Health, Warren Hall, University of California, Berkeley, Berkeley, CA 94702.

This paper was submitted to the journal February 2, 1991, and accepted with revisions September 13, 1991.

bated,[17] the more tightly diabetes is controlled before and during pregnancy, the better the pregnancy prognosis. In studies in which women have achieved and maintained normal blood glucose levels before and throughout pregnancy, the congenital malformation rate has been reduced to the rate seen in the nondiabetic population.[3,18,19]

The aim of the present study was to determine the cost-effectiveness of the CDAPP. We compared the hospital charges and lengths of stay for mothers and their infants in the CDAPP with those for a sample of births to diabetic mothers not in the program. A regression framework was used to estimate the differences in hospital charges and lengths of stay between the CDAPP group and the control group; the regression models included measures of age, race, diabetes duration and severity, and the birth weight of the child.

Methods

Study Design

We used a case-control study design and incorporated the costs of the program into the cost-effectiveness calculations. For ethical and practical reasons, we did not randomly assign women to the study group or the control group. However, we minimized the differences between cases and controls by matching participants on maternal age, ethnicity, and duration and severity of diabetes. To minimize the effect of selection bias, we chose the control hospitals from areas outside the catchment areas of the CDAPP hospitals.

Hospital Site Selection

Data for the 102 CDAPP cases were collected for all program participants at three CDAPP hospitals (Children's Hospital of San Francisco, n = 18; Sutter Memorial Hospital, n = 36; and Loma Linda University Medical Center, n = 48). We included all births to program participants between July 1, 1986, and July 30, 1988, for whom complete data could be obtained. All obstetricians who regularly delivered infants at these hospitals referred their diabetic cases to the program. Thus, virtually all of the diabetic deliveries at these hospitals were included in our data. These hospitals were selected because they were the first to implement the CDAPP and their programs were well established at the time data collection started. All CDAPP hospitals have a level 3 neonatal intensive care unit.

Data for the 218 control cases were collected from diabetic deliveries identified at five hospital sites throughout the state: Alta Bates Hospital in Berkeley (n = 89; 1984–1987), Huntington Memorial Medical Center in Pasadena (n = 71; 1985–1987), Sharp Memorial Medical Center in San Diego (n = 12; 1985–1987), St. Agnes Medical Center in Fresno (n = 15; 1985–1986), and Fresno Community Hospital (n = 31; 1985–1986). The control hospitals were selected from among hospitals that (1) were in regions that had yet to have a CDAPP implemented, (2) had at least 2000 births per year, and (3) had at least a level 2 neonatal intensive care unit.

The demographic characteristics and health status indicators of mothers and babies at these hospitals were similar. Information from the 1986 Maternal and Child Health Data Base Statistical Appendix[20] was used to compare demographic characteristics of study and control hospitals. For study and control hospitals, respectively, the average number of births in 1986 was 3867 and 4355; Black births represented 10.4% and 14.5% of total births; the percentage of women enrolled in prenatal care in the first trimester of pregnancy was 85% and 81%; the observed mortality rate was 1.8% and 1.2%; the perinatal complication rate was 17.5% and 13.8%; and the congenital malformation rate was .70% and .56%.

Only women with overt diabetes were included in the study. The severity and duration of diabetes were assessed with White's classification system[21]:

- A Asymptomatic diabetes recognized prior to pregnancy; chemical diabetes.
- B Disease that began after age 20, or that has been present for 9 or fewer years with no vascular disease.
- C Disease that began between the ages of 10 and 19, or that has been present for between 10 and 19 years with no vascular disease.
- D Disease that began before age 10, or that has been present for 20 or more years, or with vascular disease, such as background retinopathy or calcified iliac or femoral arteries.
- F Disease complicated by diabetic nephrology.
- H Disease complicated by cardiovascular disease.
- R Disease complicated by proliferating retinopathy.
- T Disease complicated by renal transplant.

Both CDAPP cases and control cases were excluded from the study if their White's classification could not be identified from the patient's medical record. Because of the very small number of cases in classes F, H, R, and T, these classes were combined with class D in a group we labeled D+.

CDAPP cases were identified by tracking enrollment records at each of the three CDAPP collection sites. Clinical and demographic data for each case were obtained from the CDAPP program database. Hospitalization charge data were collected for each mother and baby after delivery by means of the billing summary reports obtained from the hospital records. Complete billing histories were obtained for each mother for the duration of pregnancy and delivery, and for the babies from birth to discharge.

Control cases were identified by searching the computerized medical record systems for the specific ICD-9 code specifying diabetic deliveries. Billing records were then requested for the mothers and their babies to reflect all inpatient hospital admissions of the mother during her pregnancy and delivery, in addition to infant hospital charge data for the period from birth through discharge. In the event that the baby was transferred to another hospital for care, billing summaries were requested for the care delivered at the second institution.

Costs for the care provided by the CDAPP were estimated by means of "time-motion" methodology. The cost of staff time was calculated on the basis of expected staff time necessary to deliver patient care services as specified in the state *Guidelines For Care.*[22] The costs of CDAPP services were estimated on the basis of average salaries, fringe benefits, and overhead. For women who enrolled before conception, these costs averaged $1300. For late enrollees (enrolled after 12 weeks' gestation), the costs averaged $800.

The Match

To control for individual risk factors that may have an ex ante effect on hospital charges, we matched the data on mother's age, race, and severity and duration of the mother's diabetes using White's classification. Race was classified into two groups (Black and non-Black) because Black infants have been shown to be significantly different from infants of other races with respect to incidence of low

birth weight, birth-weight–specific mortality, and overall mortality. Mother's age is usually associated with risk status, especially for older mothers and the infants of younger mothers. We used three age groups (less than 20 years, 20 to 34 years, and 35 and over). Finally, White's classification was stratified into three groups: A, B and C, and D+, yielding a total of 18 possible cells.

Each CDAPP participant was randomly matched with an individual from the control group who was of the same age, ethnicity, and White's class. This procedure yielded a data set of 180 matched cases, 90 cases from the CDAPP group and 90 cases from the control group. We excluded a control group infant who incurred a hospital bill of over $1.3 million (length of stay, over 400 days). Infants requiring hospitalization beyond 6 months of age are quite rare; one was included in our sample just by chance. Including this observation would greatly increase the savings due to the CDAPP.

Variable Construction

The dependent variable is total hospital charges, which was constructed by aggregating the charges for the mothers and the babies. Charges were adjusted using the hospital component of the Consumer Price Index, so that all charges are in June 1988 dollars. Because the study hospitals are in several different labor markets across the state, a second adjustment was required. Data on wages for hospital personnel from the 1986 American Hospital Association Survey of Hospitals were used to construct a hospital-specific wage index. The hospital wage index controls for the difference in labor costs, which are the largest component of hospital costs. The average wage, weighted by the number of cases from each hospital, was used as the base for the index. Hospital-specific charges were multiplied by 1, plus or minus the percentage by which the hospital's wage differed from the weighted average wage across hospitals. Normalizing charges with this wage index makes the charges across hospitals more comparable.

The use of hospital charges to conduct a cost-effectiveness analysis has some limitations; differences in charges can be due to accounting practices or hospital inefficiencies. Length of stay is less likely to be subject to these differences. We therefore conducted a parallel analysis, using length of stay as the dependent variable. Length of stay, like charges, was aggregated for each maternal and infant hospitalization. Because both charges and length of stay have a very skewed distribution, the natural logarithms of charges and length of stay were used as the dependent variables in the regression analysis. Independent variables were included to control for risk factors that independently affect the costs of care and the length of hospital stay. These factors included maternal age, race, diabetes classification, birth weight, and source of payment. Variables were also included to test for the impact of the CDAPP.

Binary variables were used to control for the presence of these risk factors. Almost all of the births were paid for by either private insurance or MediCal (the Medicaid program for California). Therefore, a binary variable for a MediCal admission was included. Duration and severity of diabetes was controlled for with White's classifications. These classifications were aggregated into four groups: A, B, C, and D+ (includes classes F, H, R, and T). Ethnicity was controlled for with a binary variable for race (Black or non-Black). Maternal age was controlled for by including the mother's age, in years, at the time the birth occurred. Birth weight was controlled for with a set of binary variables: less than 1500 g, between 1500 g and 2500 g, and greater than 4000 g. Birth weights between 2500 g and 4000 g were the excluded category. The inclusion of birth weight in the model is appropriate because maternal diabetes tends to affect birth weight.[23,24] Moreover, previous research shows that birth weight is the single best predictor of newborn mortality and costs.[25]

To test for simultaneity bias, we reestimated the models reported below, excluding birth weight as a regressor. We also estimated models with birth weight as the dependent variable. These estimates showed no program effect on birth weight, and showed that excluding birth weight had a minimal effect on the estimated program coefficients. Thus, we are confident that any potential simultaneity bias is small.

We used several different specifications to measure the impact of the CDAPP in our regression model. The basic specification included a binary variable for our CDAPP participants. However, to test the effect of time of enrollment in the CDAPP, we created binary variables for mothers enrolled before 8 weeks' gestation and one for mothers enrolled after 8 weeks' gestation (the study did not contain enough preconception cases to allow a completely separate analysis of these cases).

Structure of the Regression Models

All of the regression models control for mother's age, MediCal status, White's class, race (Black), and birth weight, and include a CDAPP effect variable. Model 1 presents the results of the basic model. Model 2 splits the program effect variable by time of enrollment in CDAPP, the expectation being that those women who enrolled earlier would incur lower costs and length of stay. Model 3 attempts to differentiate the degree of the program effect across severity of diabetes according to White's classification system. To test for severity of diabetes, the program effect variable, a binary variable for the CDAPP cases, is interacted with the White's class variables. This procedure splits the control variable into three mutually exclusive groups by White's class (classes A and B, class C, and class D+). The controls for White's class remain in the model. The excluded category becomes control cases whose diabetes is defined by White's class A or B. Thus, the coefficient for each of these new variables gives an estimate of the differential effect of the program for each White's class group. Given the smaller sample sizes, we expected limited significance with these interaction variables.

Cost-effectiveness Calculations

Since the dependent variables for all of the models are in logarithms, direct interpretations of the charge or length-of-stay differences in the program are nontrivial. The log transformation moves the distribution toward normality, but it is still not normal. When the distribution of errors is not log-normal, the conventional formula for converting logarithms back to levels is inconsistent. Therefore, we used the smearing method developed by Duan[26] to provide consistent estimates.

The savings due to CDAPP do not occur instantly (i.e., costs of the program precede the hospital cost savings at delivery), so they must be discounted to present-value terms. To do this we allocated all hospitalization costs to the time of delivery, using an 8% discount rate. Given that these costs include maternal and infant costs, the time of delivery is probably near the midpoint of the time these costs were incurred. We used two different program patterns for this part of the evaluation. The first used the average time from entry into the program to delivery. This information was obtained from program

records for all mothers who entered the program between January 1, 1986, and December 31, 1987. Average time was calculated to be 26.5 weeks. This time reflects a mixture of pre- and post-conception enrollments. This method evaluates the program as it was actually provided; for notation purposes we refer to this as the Pre/Post analysis.

CDAPP was designed as a pre-conception program, so in our second analysis we looked at the effects of an all–pre-conception program under conservative assumptions. We assumed that the pre-conception program would yield no more benefits than would the existing mix of programs (see method 1 above), and that women in this program would take an average of 6 months to conceive once the go-ahead was given. This 6-month period, plus the estimated 3-month program time, results in an 18-month lag from time of enrollment to time of delivery. We refer to this as the All Pre analysis. To be conservative in our estimate of the program savings, we used an 8% discount rate for the evaluation. This procedure produced discount factors of 0.962 for the Pre/Post analysis and 0.891 for the All Pre analysis. Note that we are using a very restrictive definition of program savings—only the savings in maternal and neonatal costs. Longer-term medical costs due to adverse birth outcomes, which are potential savings of the CDAPP, and any potential health benefits to the mother are not included.

The discounted savings were compared with the program costs. Even though the program treatment costs were spread over time, they were all allocated to the time of initial treatment. Treatment costs of $1300 for pre-conception enrollment and $800 for post-conception enrollment were obtained from a previous analysis of the education component of the program. For the Pre/Post analysis, we used the Pre/Post mix of our sample to calculate a weighted average of $820. These costs were inflated further to reflect the program dropout rate and the failure of some participants to give birth to a live infant. Program data to date show that over 70% of the participants have given birth to a live infant, yielding effective program costs per live infant of $1857 for the All Pre analysis and $1171 for the Pre/Post analysis. These numbers are almost certainly overestimates of the per-delivery program costs, inasmuch as some of the mothers counted in these figures who ultimately will give birth to a live infant have not yet had time to do so.

TABLE 1—Cases and Controls by Selected Demographic and Clinical Characteristics

MediCal	36.3	36.2	37.8	37.8

Results

Selected demographic and clinical characteristics of the cases and controls are presented in Table 1. These characteristics are average charges and length of stay, percentage by White's class, charges and length of stay by White's class, average age of mother, percentage by specific birth-weight group, percentage by race, and percentage by payor. The relative differences between the CDAPP cases and the control group are similar for both the entire sample and the matched sample, except for those factors over which the match was stratified. For the entire sample, the CDAPP group contained women with more severe diabetes; the majority of the women in the control group were of White's classes A and B (26% and 55%, respectively), whereas the majority of the CDAPP group were of classes B, C, and D (41%, 27%, and 29%, respectively). Average length of stay was slightly higher in the control group than in the CDAPP group, for mothers as well as babies. The control group had slightly more babies in the <1500 g birth-weight group, whereas the CDAPP group had more babies in the 1501–2500 g birth-weight group. Control group mothers were slightly older, and more were Black, than mothers in the CDAPP group. The proportions of MediCal and non-MediCal payors were equal in both groups.

When all cases are included, the control group charges (for mother and baby combined) were 23% higher than those of the CDAPP group ($18 449 vs $14 958). For the matched cases, the combined charges of the control group were 41% higher than those of the CDAPP group ($21 699 vs $15 344). Most of this difference can be attributed to charge differences for the babies, particularly in the matched comparison ($10 674 for controls vs $5918 for CDAPP). Charges and length

*$P \leq .05$ (one-sided).
**$P \leq .01$ (one-sided).

of stay increased with the severity of diabetes. Patient charges were higher when Medicaid was the primary payor, and within this group, the charges for the control cases were always higher than those for the CDAPP cases. Blacks incurred higher average charges than did non-Blacks, across the board. Among non-Blacks, charges were much lower for the CDAPP cases than for the control cases, whereas there was essentially no difference in charges for Blacks.

Table 2 contains charges for CDAPP participants by length of gestation at program enrollment: before 8 weeks (this group includes the pre-conception enrollees) and after 8 weeks. The 8-week cutoff was used because this is the time in organogenesis when major congenital malformations can occur. Lower maternal and infant charges were incurred by the women enrolled earlier in the program (the charges of the after–8-week group were 44% higher than those of the before–8-week group). The length-of-stay comparisons follow a similar pattern.

We now turn to the results of the regression analysis. The coefficient estimates and *t* statistics for model 1 are shown in Table 3. For a one-tailed test, *t* statistics above 1.65 are statistically significant at $P < .05$. This table reports four sets of estimates: two dependent variables (log of wage and inflation adjusted charges and log of length of stay) for two data sets (all observations and the matched data). Because the dependent variables are in logarithms, for each continuous variable (e.g., age) in the regression model, each coefficient is the estimate of the percentage effect on the dependent variable of a one-unit change in the independent variable. For binary variables, the simple interpretation that the coefficients show the percentage difference in charges or length of stay for the presence or absence of that factor is biased.[27] The actual percentage effect of the coefficient can be accurately approximated by $\{(\exp(c))-1\}$, where c is the coefficient estimate. The size of this bias increases with the coefficient estimate. For a coefficient of 0.25, the true percentage effect is 0.28 (28%); for an estimate of 0.50, the percentage effect is 0.65.

For exposition, we will work through the meaning of the coefficients of the first column of Table 3 (model 1). Because of the adjustments required for binary variables, discussed previously, we report two numbers in the text for each coefficient for all binary variables—the actual estimate and the adjusted estimate, indicated in parentheses. The maternal age effect is very small: hospital charges decreased by 0.6% for each year that maternal age increased. However, the coefficient is not statistically significant; therefore, this effect should be considered to be zero. Compared with White's class B (the reference group), cases in White's class A incurred charges that were 47.0% (37.5%) lower, cases in White's class C incurred charges that averaged 41.5% (51.5%) higher, and cases in White's class D+ incurred charges that averaged 54.5% (72.4%) higher. Charges to MediCal mothers averaged 30.9% (36.2%) higher than those covered by private insurance.

Charges for Black mothers averaged 25.4% (28.9%) more than those for non-Black mothers. A key finding is that mothers and babies in the CDAPP incurred charges that averaged 30.3% (35.3%) lower than charges for the control cases. Hospital charges and length of stay increased rapidly as birth weight decreased from the normal-weight range of 2500 g to 4000 g. However, there were no differences in charges and length of stay between normal-weight cases and cases with birth weights over 4000 g. The adjusted R^2 of 0.259 indicates that the model explains 25.9% of the variance in the logarithms of total charges.

Because the effects of the control variables are stable across models, we report the coefficient estimates for the program effects of the other models in Table 4. To facilitate comparison with models 2 and 3, we repeat the estimates of the program effect for model 1 in Table 4. For model 1, CDAPP cases incurred charges that were 30.3% (35.3%) lower for the entire sample and 24.7% (28.0%) lower for the matched sample. CDAPP cases' length of stay was 26.2% (30.0%) shorter for the entire sample and 19.2% (21.1%) shorter for the matched sample. When the regression results are converted to dollars and days (by applying Duan's correction[26]), they represent average reductions for each mother and baby of $7692 and $6312 in charges, and reductions in length of stay of 5.1 and 4.0 days, for the entire sample and the matched sample, respectively.

Model 2 breaks the program effects into early and late enrollment. Early enrollment reduced length of stay by 39.6% (48.6%) and charges by 34.5% (41.2%) in the entire sample. In the matched sample, early enrollment reduced length of stay by 34.6% (41.4%) and charges by 29.5% (34.4%) not significant (NS). Late enrollment reduced charges by 28.9% (33.5%) and length of stay by 21.2% (23.6%) for the entire sample, and reduced charges by 23.3% (26.2%) and length of stay by 14.0% (15.0%) (NS) for the matched sample. When these results are transformed into dollar or days terms, they represent reductions for early enrollees of $8759 and $7539 in charges and 7.7 days and 7.2 days in length of stay for the entire sample and the matched sample, respectively. For late enrollees, the corresponding reductions are $7344 (entire sample) and $5941 (matched sample) and 3.1 days (entire sample) and 2.9 days (matched sample).

Model 3 was used to examine the differential effects of the program across severity of diabetes. Interpretation of the program effects is more complex for this model, because the effects of White's class must be included. The excluded category is control cases in White's class A or B. To compare a group with the excluded category, the White's class variable is added to the interaction variable between the CDAPP group and White's class. For the most severe cases of diabetes (D+), charges were 51.0% (66.6%) and 65.8% (93.2%) lower than charges for control cases for the matched sample and the entire sample, respectively. Length of stay was 29.4% (34.2%) (NS) and 48.8% (62.9%) shorter for the matched sample and the entire sample, respectively. For class D+, the retransformed charges for the CDAPP group were $16 766 lower than charges for the control group. Except for length of stay for the matched sample for White's classes A and B, the coefficient estimates for the less severe diabetics are not statistically significant. In sum, the savings were larger for the most severe cases of diabetes (those in class D+). However, these numbers must be treated with some caution owing to the reduced sample sizes, especially for class D+.

These models were reestimated with the maternal and infant components of charges and length of stay as separate dependent variables. Overall, the program had similar effects for mothers and infants. We also found no difference in the estimated program effects between Blacks and non-Blacks and between MediCal and other payors.

Note. These models control for mother's age, White's class of diabetes, insurance (MediCal), race (Black), and birth weight. The estimated dependent variables are log charges and log length of stay for mothers and babies. *T* statistics are given in parentheses.
*$P \leq .05$ (one-sided).
**$P \leq .01$ (one-sided).

The savings estimated from the regression models were discounted to make them directly comparable with program costs. Table 5 shows these discounted savings. Turning first to the results for model 1, we report the most conservative estimate (the matched group) of the savings generated by the CDAPP. For the Pre/Post CDAPP group, the savings were $6072 per participant. If all women went into the program before conception (preconception) the savings would be $5624 per participant, because the CDAPP costs are higher for this group. Model 2, which shows estimated program savings for early and late enrollees, indicates that savings for early enrollees (those who enrolled within 8 weeks of conception) were $7253, compared with $5715 for late enrollees. The results for the entire sample are similar and are slightly larger in most cases. The larger program costs under the All Pre assumption lead to slightly smaller net savings. Model 3 shows that the savings increased with the severity of diabetes. The counterintuitive result for White's class C in the matched sample may be due to the relatively small sample size (NS).

The cost-effectiveness of the CDAPP is calculated by comparing the discounted savings shown in Table 5 with the program costs. This is done by subtracting the program costs from the discounted savings to obtain net savings. To make this calculation meaningful, we allocated to the CDAPP all expenditures incurred during

TABLE 5—Discounted Savings (in dollars) for Models 1, 2, and 3

	All Cases		Matched Cases

Note. Assumes 70% of program participants ultimately give birth to live infants. All pre: $1300 to $1857 per CDAPP participant. Pre/post: $820 to $1171 per CDAPP participant.

[a] Total Discounted Savings/Program Costs (these are costs of program)

our study period. This procedure produces a downward bias in our savings (i.e., savings will be lower), because additional savings will come as other CDAPP participants have additional children. Both the Pre/Post cost of $1171 and the All Pre cost of $1857 are markedly less than the estimated savings for all of the models.

Alternatively, the gross savings can be divided by the program costs to obtain a cost-effectiveness ratio. This ratio measures the short-term savings per dollar spent on the CDAPP. These ratios are presented in Table 6. We find that for the matched sample, the CDAPP has a cost-effectiveness ratio of 5.19; this means that for every $1 spent on the CDAPP there is an estimated savings of $5.19. These ratios also show the marginal effectiveness of applying the program to different subsets of the study population. The largest returns will be realized if the program targets early enrollees and more severe cases of diabetes. The returns are smaller for late enrollees, and smaller and not statistically significant for less severe cases of diabetes.

Discussion

The CDAPP has a statistically significant effect that lowers hospital charges and length of stay for diabetic mothers and their infants. Moreover, the program is cost-effective and returns over $5 for every $1 spent. The conservative assumptions used in the analysis suggest that the actual savings due to the CDAPP are larger than our estimates.

Comparisons of demographic characteristics of the women who gave birth in the CDAPP (from preliminary program status reports) and women who gave birth in the general population in California in 1986[20] show that these groups are quite similar. Data on three pregnancy risk factors—maternal age, prenatal care in first trimester, and race—were considered. In the high-risk age group, 4.0% of all California births were to women under 18 years old, compared with 3.6% of births in the CDAPP; 8.8% of all births were to women over 35 years old, compared with 21.4% of births in the CDAPP. Of all births, 74% were to women who began medical care in the first trimester of pregnancy; 67.2% of births in the CDAPP were to women with overt diabetes who joined the CDAPP in the first trimester. Of all births, 10% were to Black women; 7% of births among the overt diabetics in the CDAPP were to Black women. These comparisons suggest that our results are quite generalizable to California mothers.

The program is more cost-effective if the mothers enroll before conception, or shortly thereafter. Our estimates show that early enrollees incur lower hospital charges and have shorter stays. Although late enrollees also incur lower charges and have shorter stays, the CDAPP effects are smaller. It is conceivable that when the CDAPP is fully implemented, early program participation will be increased. If this occurs, our estimates suggest that the program savings will increase. The program savings for early enrollees are 10% to 15% larger than those for late enrollees. Declines in length of hospital stay are even larger. Further, the program is more cost-effective for those mothers with more severe diabetes (White's class D+).

The lack of statistical significance in model 3 for White's classes A and B and class C does not mean that the program is not effective for these cases. Given the relatively large variation in costs and length of stay and the smaller expected effects for less severe diabetics, it is possible that our sample was not of sufficient size to enable us to detect differences for these groups. Further study is needed to determine whether the program actually reduces costs and length of stay for these less severe cases.

Our overall finding is that the CDAPP yields substantial short-term economic savings. If 2598 babies are born to women with overt diabetes in California in 1990, as estimated by the California Department of Health Services in 1987, the estimated yearly savings attributable to the CDAPP will be between $14 million and $19 million, depending on how many women enroll in the program before conception. In addition to the short-term economic savings of the program, there are unmeasured savings that have not been captured in our estimates. Improved glucose management will likely result in improvements in the future health status of the mothers, assuming that they retain the knowledge they gained while in the program. Reductions in the severity of birth complications will likely result in fewer anomalies and other handicaps, yielding long-term savings due to reduced medical and educational expenses and increased future productivity. With a more normal pregnancy and a healthy baby, a working mother can remain in the work force longer and return to work sooner. The reduction in perinatal problems may minimize disruption of the father's ability to work, as well. In addition, there are many nonmonetary benefits to healthy pregnancy outcomes. □

Acknowledgments

This study was funded by the California Department of Health Services, Maternal and Child Health Branch (contract 88-93733).

The support, time, and energy of many individuals contributed to the success of this study. We would like to express our gratitude to Diana Lee, RD, MPH, Joe Brazie, MD, MPH, Donna Dahrouge, MPH, and Jan Pierce, who all played essential roles in the initiation and completion of the study. We also wish to thank Larry M. Cousins, MD, Jack Kitzmiller, MD, and Carol Korenbrot, PhD, for their useful comments and suggestions on an earlier draft. Lastly, we extend our gratitude to the staff of the medical and billing records departments of all of the hospitals we visited for providing the data needed for this study.

Maternal Smoking and the Risk of Polyhydramnios

Wendie Myhra, MSN, MPH, Margaret Davis, DVM, MPH, Beth A. Mueller, DrPH, and Durlin Hickok, MD, MPH

ABSTRACT

Background. Washington State birth certificates were used to conduct a population-based case-control study to assess the possible association of maternal smoking with polyhydramnios.

Methods. All singleton births complicated by polyhydramnios (n = 557) were identified from the vital records for the years 1984 to 1987. For comparison, 1671 records were randomly selected for the same years from singleton births uncomplicated by polyhydramnios.

Results. Women who reportedly smoked prenatally were found to be at increased risk for polyhydramnios (relative risk [RR] = 1.7, 95% confidence interval [CI] = 1.5–2.1, adjusted for marital status, maternal age, and parity). When women with conditions known to be associated with polyhydramnios were excluded, the risk for those who smoked prenatally remained elevated (RR = 1.8, 95% CI = 1.1–2.3).

Conclusion. Overdistention of the uterus from polyhydramnios may cause a variety of pregnancy complications. The observed association of smoking with polyhydramnios may be a further indication for public health interventions aimed at preventing smoking during pregnancy. (*Am J Public Health.* 1992;82:176–179)

Introduction

Polyhydramnios, an excess of amniotic fluid during pregnancy, is a condition whose causes and implications are not completely understood. Although it is known that polyhydramnios occurs more often in women with established and gestational diabetes, multiple pregnancies, and pregnancy complications such as preeclampsia, as well as in women whose babies have congenital malformations, the mechanism by which it occurs is poorly understood. In addition, polyhydramnios is reported with greater frequency than can be explained by these conditions alone.[1,2] Thus, to understand better the possible causes of polyhydramnios, we carried out a population-based case-control study using birth certificate data.

Methods

A total of 277 043 singleton births were recorded on the Washington State birth certificate tapes from 1984 through 1987. Of these, 557 pregnancies were reported to be complicated by polyhydramnios. A control group consisting of 1671 singleton births was randomly selected from among those births for which polyhydramnios was not indicated as a complication. The Washington State birth certificate contains a check-box format, which has been shown to provide more complete reporting of birth complications.[3] This information was collected, as were data on maternal and infant characteristics, complications of pregnancy and labor, and congenital malformations.

A stratified analysis was conducted using the Mantel-Haenzel estimator of the odds ratio, and 95% confidence intervals (CIs) were calculated using Cornfield's method.[4] Several variables were considered as potential confounders; these included maternal age (under 35 years, 35 years and over), race (White, Black, other), marital status, smoking status during present pregnancy, parity (zero, one or more), urban or rural residence, income level of census tract of residence, trimester of first prenatal care, sex of infant, complications of pregnancy, congenital malformations, prior fetal deaths (fewer than 20 weeks gestation, 20 to 36 weeks gestation, more than 36 weeks gestation), and season of birth. However, only those variables that affect the relative risk (RR) estimate were retained for analysis.

The initial analysis was carried out using the entire study population. The majority of subsequent analyses were restricted to White women only because there were very few non-White subjects and the small number made attempts to control for race unsuccessful.

Results

A greater proportion of cases than of controls were aged 35 years or older, un-

married, and of higher parity (Table 1). The proportion of cases with gestational or established diabetes or with preeclampsia was also higher than that for controls, and a greater proportion of cases than controls experienced complications such as abruptio placentae or placenta previa, or delivered a baby with a congenital anomaly. Although the great majority of both cases and controls were White, the proportion of Black cases was nearly twice that of Black controls, and among Hispanics there was a relatively lower proportion of cases (1.6%) than of controls (2.6%).

Among Whites, the proportion of cases who smoked (34.5%) was greater than that for controls (23.8%), resulting in an increased risk among cases for polyhydramnios (RR = 1.7, 95% CI = 1.5–2.1, adjusted for maternal age, marital status, and parity) (Table 2). White women who were 35 years of age or older were at increased risk for polyhydramnios (RR = 2.6, 95% CI = 1.6–3.2, adjusted for marital status, smoker status, and parity), relative to those aged 20 to 34 years of age. The risk for polyhydramnios also increased with increasing parity. White women having one previous birth compared with those having no previous births were at a slightly increased risk for polyhydramnios (RR = 1.2, 95% CI = 1.0–1.5), and those with three or more previous births had nearly twice the risk for polyhydramnios (RR = 1.9, 95% CI = 1.2–3.3). (These risks were adjusted for maternal age, smoker status, and marital status.)

After excluding women with preeclampsia, established and gestational diabetes, and babies with congenital malformations, the risk of polyhydramnios associated with maternal smoking among White women was 1.8 (95% CI = 1.1–2.3) (Table 3). The risks associated with maternal age of 35 years or older increased slightly as well, to 3.1 (95% CI = 1.9–5.3). The risks associated with higher parity remained consistently elevated.

Women with established diabetes were at a greatly increased risk for polyhydramnios (RR = 23.9, 95% CI = 5.2–957.0). Those with gestational diabetes had a risk of 7.3 (95% CI = 3.2–18.3), and those with preeclampsia had a risk of 2.8 (95% CI = 1.8–4.9). (All risk estimates were adjusted for maternal age and the presence of fetal malformations.) The risk estimates for gestational diabetes and preeclampsia were also adjusted for smoker status.

In contrast to the risk estimate for polyhydramnios associated with smoking among White women, the risk among Black women was less than 1, even after adjusting for maternal age (RR = 0.6, 95% CI = 0.1–1.9). Adjusting for parity, marital status, gravidity, diabetes, preeclampsia, or the presence of congenital malformations did not effect the risk estimate. The number of Black cases and controls was too small to adjust for all variables simultaneously.

Discussion

These results suggest that maternal smoking during pregnancy is associated with an increased risk for polyhydramnios, even in the absence of other recognized risk factors. To our knowledge, this association has not been reported previously. Our finding of an increased risk for polyhydramnios associated with the pres-

ence of gestational diabetes, established diabetes, preeclampsia, and congenital malformations is consistent with earlier reports.[1,2,5–7]

In addition, these data suggest that the risk of polyhydramnios increases with increasing parity. Women with one previous birth are at a slightly increased risk for polyhydramnios, and those with three or more previous births are at nearly twice the risk, compared with those with no prior births; this remains true even after adjusting for maternal age, smoking status, and marital status. It is possible that this apparent association occurs because women with prior births may have had polyhydramnios as a complication of a previous pregnancy. Whether a history of polyhydramnios increases the likelihood of developing polyhydramnios in subsequent pregnancies is unknown. However, women with histories of gestational diabetes, of carrying a malformed fetus, and of other complications in pregnancy are more likely to experience these complications in subsequent pregnancies than are women with no such histories. Thus, it is plausible that the association with parity seen in this study may, in part, be due to an association with these adverse occurrences in prior pregnancies.

Increased maternal age was also a risk factor for polyhydramnios, even after adjusting for parity, smoking, and marital status and excluding pregnancies with complications associated with polyhydramnios and those resulting in the birth of a baby with congenital malformations.

Several biological mechanisms might explain the apparent association between cigarette smoking and polyhydramnios. There is experimental evidence that lactogenic hormones are involved in regulating fluid flux across placental membranes.[8] A decrease in human placental lactogen has been demonstrated in smokers,[9] and chronic idiopathic polyhydramnios has been shown to be associated with a deficit in chorionic laeve prolactin receptors.[10] A deficit in human placental lactogen could have the same effect as a deficit in receptors.

The relationship between smoking and polyhydramnios may also be mediated by the hormone angiotensin, which functions in the control of vascular volume. Angiotensin I (AI) is normally converted to angiotensin II (AII) in the lung by angiotensin-converting enzyme (ACE). AII is associated with peripheral vasoconstriction. Human and animal studies have shown that smoking elevates ACE levels and enhances activation of the angiotensin system.[11–13] A connection between the angiotensin system and the development of polyhydramnios is supported by animal models in which infusion of AI into fetal lambs induced polyhydramnios.[14]

Finally, polyhydramnios may be linked to changes that occur in placental vasculature as a result of cigarette smoking. Nicotine reduces placental blood flow in humans and animals.[15–17] Microscopic placental examination has demonstrated atrophic and hypovascular changes in the placental villae of smokers, suggesting that prenatal smoking results in impaired uteroplacental circulation.[9]

The relatively "soft" nature of the method by which polyhydramnios is diagnosed constitutes a limitation to this study. *Williams Obstetrics*[18] defines polyhydramnios as more than 2000 mL of amniotic fluid. Until very recently,[19] no attempts were made to measure normal amniotic fluid volumes in a large population of pregnant women.[7,19] Although available,[20–22] objective sonographic criteria for the diagnosis of polyhydramnios may not always be applied. Because of this, the diagnosis of polyhydramnios often relies on the subjective clinical judgment of each woman's health care provider. Our method of case ascertainment is limited to a yes/no variable from the birth certificate, without any knowledge of how the diagnosis was made. Births with labor complications may be more likely than others to be recorded as having been complicated by polyhydramnios. Ultrasound examination, often indicated for conditions of pregnancy known to be associated with polyhydramnios, is also a method of case finding. Both of these mechanisms might possibly result in underreporting of idiopathic polyhydramnios. However, this would have led to a conservative bias in our risk estimate.

Our indicator of a woman's smoker status is also limited in that it does not allow any measurement of the dose of cigarettes smoked or of the duration of smoking during pregnancy. It is most likely that our variable for smoking reflects a woman's smoker status at the time of her first prenatal visit, as this is when this item of her medical record is checked. Many smokers change their behavior while pregnant,[23] so it is likely that some women who stopped smoking during their pregnancies were misclassified in the smoker category. Again, this would have had the effect of biasing our risk estimates toward the null.

Another limitation is that our data were limited to live births. Fetal losses and elective terminations of pregnancy were not included in the study, resulting in possible bias. Spontaneous abortion is often associated with fetal anomalies, and it shortens pregnancies that, had they continued, might have been complicated by polyhydramnios. Induced abortions following early detection of congenital malformations by alpha-fetoprotein screening or amniocentesis may also result in a decreased number of polyhydramnios cases with malformations. These two mechanisms would result in an underestimation of the true relative risk associated with the presence of malformations.

In this population, the prevalence of polyhydramnios at birth was 0.2% com-

pared with ranges in other reports from 0.2% to 1.7%. The observed variance in prevalence may be due to the subjective nature of the diagnosis and to the differences between populations studied.[1,5,6,24] Most prior investigations of polyhydramnios have been limited to hospital or clinic-based series, and our population-based figure appears to lie well within this range. Further population-based studies, using strict criteria, would provide a better understanding of potential risk factors and outcomes associated with polyhydramnios.

Overdistention of the uterus from polyhydramnios may cause a variety of pregnancy complications, including inefficient uterine action resulting in preterm labor, abruptio placenta, abnormal fetal lie, and dystocia.[6,25] Therefore, polyhydramnios may elevate a woman's risk for complications even in the absence of other known risk factors.[4,23] The possible association of smoking and polyhydramnios is an added indication for public health interventions aimed at preventing smoking during pregnancy. □

A Cost-effectiveness Analysis of Three Staffing Models for the Delivery of Low-Risk Prenatal Care

Elaine A. Graveley, DBA, RN, and John H. Littlefield, PhD

ABSTRACT

Background. Health care costs are increasing at more than twice the rate of inflation, thus, public officials are seeking safe and economic methods to deliver quality prenatal care to poor pregnant women. This study was undertaken to determine the relationship between the cost and effectiveness of three prenatal clinic staffing models: physician based, mixed staffing, and clinical nurse specialist with physicians available for consultation.

Methods. Maternal and neonatal physiological outcome data were obtained from the hospital clinical records of 156 women attending these clinics. The women were then interviewed concerning their satisfaction with their prenatal care clinic. The financial officer from each clinic provided data on the clinic staffing costs and hours of service.

Results. There were no differences in outcomes for the maternal–neonatal physiological variables, although newborn admission to the Neonatal Intensive Care Unit (NICU) approached significance among the clinics. The clinic staffed by clinical nurse specialists had the greatest client satisfaction and the lowest cost per visit.

Conclusions. The use of clinical nurse specialists might substantially reduce the cost of providing prenatal care while maintaining quality, and might thereby save valuable resources. (*Am J Public Health.* 1992;82:180–184)

Introduction

With health care costs growing at more than twice the rate of inflation, public officials are seeking safe and economic methods to deliver quality health care to indigent populations. The percentage of indigent individuals who receive quality health care is decreasing. Lewin[1] reported that, from 1976 to 1983, Medicaid covered a decreasing number of the poor (of the population with incomes below the poverty line, 65% were covered by Medicaid in 1976 and 53% in 1983) and that poor pregnant women have been increasingly underserved as a result of budget cuts and policy changes.

The relationship between low-birthweight (LBW) babies and the absence of prenatal care is well documented.[2–4] The Office of Technology Assessment (OTA) estimated that for every LBW birth averted, between $14 000 and $30 525 in newborn and long-term health care costs could be saved.[5] OTA also analyzed the cost-effectiveness of expanding Medicaid coverage to all poverty-level pregnant women in an effort to provide them with early prenatal care. Their conclusion was that such expansion would be cost effective and would be a good investment for the nation.

The National Commission to Prevent Infant Mortality (NCPIM) also studied the problem of LBW and proposed universal access to early maternity care for all expectant mothers.[6] However, neither NCPIM nor OTA recommended the type of health care provider for these additional 194 000 women.[5] With our increasingly litigious society, the number of obstetricians willing to serve Medicaid patients is declining. There are, however, other models of prenatal care that need to be studied for their cost-effectiveness: individual or group physician-based clinics and, depending on state laws, nurse-based clinics that tie medical practice with a nurse midwife, nurse practitioner, or clinical nurse specialist. The focus of this study was a comparative cost-effectiveness analysis of three low-risk prenatal clinic staffing models: physician based, mixed staffing (physician, nurse practitioner, registered nurses, nurse aides), and nurse based. Low-risk prenatal care was defined in this study as care given to a pregnant woman "whose complaint or problem has been resolved, or does not pose a threat to life."[7] The results of this study should be helpful to public policymakers who are implementing OTA's and NCPIM's proposal to increase the availability of prenatal care for indigent patients.

Methods

Clinics

The three clinics served predominantly Hispanic clients of low socioeconomic status and referred all women with complications to the Complicated Obstetrical Clinic at the community health center. The women primarily delivered at the hospital operated by the county hospital district.

Clinic 1. This private-not-for-profit entity was funded under Titles 329 and 330 of the Public Service Health Act and served as the physician-based clinic

(MDC) in this study. Women saw the same physician for all their prenatal care and counseling and received a standard clinic appointment. Fees were charged on a sliding scale, according to the woman's ability to pay.

Clinic 2. This clinic, one of 19 operated by the city health department, served as the mixed-staffing clinic (MSC). The clinic was located within the same catchment area as the MDC. Each patient saw a nurse aide, a registered nurse for prenatal teaching, and the nurse practitioner and/or contract physician at each visit. The clinic operated twice a week from 8 AM to 12 noon. All women received an 8 AM appointment, and prenatal care and counseling were provided for $50 unless the woman was unable to pay.

Clinic 3. This clinic was jointly operated by the county hospital district and the local University Health Science Center's School of Nursing and Department of Obstetrics and Gynecology and served as the nurse-based clinic (RNC). The clinic was located within the county community health center. Three clinical nurse specialists delivered total prenatal care, including referrals to community agencies. Fees were charged on a sliding scale, according to the woman's ability to pay, and the women received a standard appointment time.

Subjects

The sample size, 156 subjects, was determined by a power analysis of 3 months of birth-weight data from women who attended the clinics and delivered at the county hospital ($\alpha = .05$, effect size = .25, power = .8; 3 groups). The study sample was drawn over a 3-month period in 1989 from women who had delivered at the county hospital. To be included, subjects had to: (1) be 18 years of age or older, or emancipated minors; (2) have obtained their prenatal care at one of the three clinics with a minimum of three prenatal visits (three visits was considered the minimum for the woman to have sufficient experience to validly report her satisfaction with her prenatal care clinic); and (3) have delivered within 48 hours of the interview.

Potential subjects were identified from their hospital record and asked to participate in a study of prenatal care clinics. No potential subject was excluded because of language, a Spanish interpreter was available to all women, and none of the women declined to participate.

TABLE 1—Variables Studied

Demographic	Physiological	Satisfaction	Cost
Ethnicity	Maternal	Patient satisfaction tool	Personnel
Age	Weight gain		Hours delivering prenatal care
Education	Hemoglobin		Consultation (nurse-based clinic)
Medicaid	Complications at the time of delivery		No. of appointments made/kept
Marital status	Neonatal		
Gravida	Weeks of gestation		
No. of prenatal visits	Birth weight		
Adequacy of prenatal visits	Apgar score		
Prenatal classes	Admission to Neonatal Intensive Care Unit		

Determining Pregnancy Outcomes and Satisfaction

Four broad categories of patient variables were analyzed: demographic, physiological, satisfaction with care, and cost (see Table 1). The physiological variables related to low-risk prenatal care were gathered from previous prenatal research studies.[5,6,8] The Kessner Index[9] was used to assess the adequacy of prenatal visits. This index categorizes prenatal care as adequate, intermediate, or inadequate depending on the weeks of gestation and the number of prenatal visits. Differences in the number of laboratory tests among the clinics could not be determined, as one clinic denied access to its patient records. However, both the MSC and RNC nurses used similar screening protocols and had similar guidelines for physician consultation.

Maternal satisfaction with access to care was assessed via a patient satisfaction tool[10] (PST) consisting of 27 statements that the subject rated on a 6-point Likert scale. The statements addressed five categories of satisfaction: accessibility, affordability, availability, acceptability, and accommodation. Five scores, one for each category, were generated by the PST. The readability index of the PST was at the fifth-grade level, and the internal consistency reliability coefficient was reported as .83. Both an English and a Spanish version of the tool were available to the subject. The interview took approximately 20 minutes to complete.

Determining Costs

The financial officer of each clinic provided data on five variables for study: number of staff, hourly wages (see Table 2), number of prenatal appointments made and kept, and number of hours spent delivering prenatal care. The RNC nurses kept a flowchart of the number of times they conferred with a physician and the time involved in order to determine the cost of consultation. The cost of the consultation time was computed on the basis of the hourly salary for the MSC contract physician. No physical facility costs were included in the analysis, as they were not considered germane to determining the clinics' staffing model costs.

Cost per clinic visit was determined by dividing the personnel costs by the number of kept appointments. Clinic productivity was determined by dividing the number of patients seen for prenatal care by the number of hours spent delivering prenatal care. In a cost-effectiveness analysis, the differences among the clinic costs and appointment outcomes are calculated using percentage differences. The staffing model with the lowest outcome value or cost item is identified, and then the percentage differences between this model and the other two models are calculated.[11]

Results

Demographic Variables

Subjects at the three clinics did not differ significantly on any of the demographic variables except ethnicity, years of education, and Medicaid coverage (see Table 3). Compared with the MDC and MSC, subjects at the RNC were less likely to be Hispanic, more likely to have graduated from high school, and more likely to be on Medicaid. These significant variables were further evaluated using χ^2 analysis to assess their relationship to the neonatal outcome variables. None of the χ^2 tests were significant.

Analyses of variance (ANOVAs) were computed to assess the relationship between patient ethnicity, educational level, and Medicaid coverage with satisfaction as measured by the PST. Ethnicity

Note. MDC = physician-based clinic; MSC = mixed-staffing clinic; RNC = nurse-based clinic.
[a]Part-time.

and Medicaid coverage were not significantly related to any of the PST statements.

Educational level was statistically significant for two PST statements ("I saw the same physician/registered nurse for all my prenatal care" and "The fees at the clinic were more than I wanted to pay"). These two statements were further analyzed using a Student Newman-Keuls post hoc *t* test to investigate pairwise differences. For the first statement ("saw the same physician/registered nurse"), those subjects with 12 years of education differed significantly from the group with 8 to 11 years of education. Cross tabulation, controlling for clinic, was done for each group; the 19 subjects who responded "never" to the statement were from the MSC. A Student Newman-Keuls test for the statement referring to the fees being too high showed that all educational levels differed significantly from the group with 0 to 7 years of education. The lower educational group was the only one in which all members (n = 4) indicated that the fees charged were "never" fair. Each clinic was represented in this group. Ninety-four percent (n = 147) of the subjects responded that the fees were "always" fair.

Analysis of the subject's reported cost for her prenatal care was done using an ANOVA. The ANOVA was significant, $F(2, 156) = 28$, $P = .000$. The grand mean for the three clinics was $29.40; the means for the individual clinics were $59.54 for MDC, $8.71 for MSC, and $19.16 for RNC. Fifty-six percent of the subjects (n = 88) reported that they paid nothing. A Pearson's *r* showed no significant relationship between subject-reported costs and the number of prenatal visits. Also, there was no significant relationship between the clinics' charge to each subject for her prenatal care, the maternal/neonatal physiological variables, and NICU admission. These differences in subject demographic data, therefore, did not appear to be related to the categorical dependent variables in the study.

Physiological Outcomes

There were no significant differences among the clinics for any of the maternal physiological variables. Twenty-eight percent (n = 20) of the subjects had an inadequate number of prenatal visits; the mean hemoglobin level at the time of hospital admission for delivery was 12 g, the mean weight gain was 30 lb, and there were no documented maternal complications at the time of delivery.

Babies of the subjects of the three clinics did not differ on any of the five neonatal variables: 85% (n = 133) were between 38 and 42 weeks of gestation, 86% (n = 134) weighed between 2500 and 4000 g, 28% (n = 43) were admitted to the NICU, 85% (n = 132) were discharged with their mother, and there were no fetal deaths or baby deaths within the first 48 hours of life.

Maternal Satisfaction

The PST internal reliability coefficient in this study was .76. ANOVA tests revealed no significant differences among the clinics for the satisfaction categories of accessibility and affordability. A Student Newman-Keuls post hoc *t* test showed the significant differences among the mean scores for the other groupings (see Table 4).

Cost Data

Table 5 shows the cost and outcome data per clinic and Table 6 shows the percentage differences among the clinics for the supplied data. Although the MSC had the lowest personnel costs, the RNC had the lowest cost per clinic visit and the highest productivity.

Discussion

The absence of significant differences among the three clinics for the maternal–neonatal physiological variables was expected and supports other reports that nurses prepared for a specific area of health care can provide quality care.[7,12–15] The number of NICU admissions approached significant differences, with the MSC having 35% (n = 20) of its subjects' babies admitted compared with 21% (n = 11) for the MDC and 23% (n = 12) for the RNC. The number of complicated pregnancies referred to the health center by each clinic was not analyzed. It is possible that the MSC referred fewer complicated pregnancies and therefore increased its number of NICU admissions. As 35% is higher than the 28% average number of newborn NICU admissions (level 1, 2, or 3) for this hospital, this

may deserve further research.[16] However, it did not affect the conclusions of this study.

The RNC subjects indicated significantly higher satisfaction than the MDC subjects in the access-to-care dimension of accommodation and overall satisfaction. This finding supports the studies, cited by OTA,[5] that reported patients often found that nurse practitioners exhibited more interest, reduced the professional mystique of health care delivery, conveyed more information, and were more skillful than physicians when providing services that depended on communication with patients.

However, the subjects at the MDC, which had no nurse practitioners, indicated significantly greater satisfaction with availability and accommodation and had a higher total satisfaction score than the subjects at the MSC, which had one nurse practitioner. One explanation for this might be that at both the MDC and RNC, subjects had only one caregiver throughout their pregnancy. All MDC and RNC subjects were able to name their care provider, while not one MSC subject could name a single individual who either had given her care or had provided health education during her prenatal visits. Subjects at the MSC saw a physician and/or nurse practitioner at each visit; however, it was not necessarily the same individual. In addition, the MSC policy of not making specific patient appointments, with the subjects sometimes waiting several hours for an appointment, was cited by many subjects as being very difficult. Lowered subject satisfaction with the MSC was probably due to its policy regarding block appointments and limited time spent with any care provider.

Prenatal care costs were based on data provided by the clinic financial officers. Costs were based on 15 minutes per visit at the MDC and 30 minutes per visit at the RNC; for the MSC costs were based on preset times for each personnel category during each 4-hour period of clinic operation. For example, during this study the clinic clerk at the MSC was assigned only 26 hours of the scheduled 104 hours of clinic operation. In addition, this clinic was frequently open for more than 4 hours, which was not accounted for in the supplied cost data. Therefore, the MSC personnel costs and cost per visit might actually be higher and their productivity lower than reported in Table 5. The lower cost per RNC appointment was primarily due to limited use of physician time, which is the most expensive resource in delivering low-risk prenatal care.

Note. PST = patient satisfaction tool; MDC = physician-based clinic; MSC = mixed-staffing clinic; RNC = nurse-based clinic.
[a]Significantly lower score compared with MDC and RNC.
[b] Significantly lower score compared with RNC.

Discussions with the RNC staff concerning the time spent waiting for physician consultation and the physician's changes to a proposed plan of care suggest the potential value of a yearly review of clinic patient care protocols by the nurse–physician team. This review would help to reduce the nonproductive waiting time for the clinical nurse specialists.

Both the RNC and the MSC had 27% missed appointments, compared with 18% at the MDC. A high incidence of missed appointments ultimately increases clinic costs because fixed personnel expenses are expended without delivering care. The lower missed-appointment incidence at the MDC may be attributed to the effectiveness of its caseworker, who called patients with missed appointments, discussed with them the importance of their clinic visits, and then tried to reschedule them.

Qualitative data can be very useful in studies of health care delivery.[17,18] This study of staffing models found significant differences in patient satisfaction and cost-effectiveness. Qualitative data from patient interviews helped ascertain that lower satisfaction with the MSC was due in part to clinic scheduling policies. In a similar vein, differences in the number of missed appointments were due in part to an effective caseworker in the MDC. These qualitative data are critically important to field studies of health care delivery that, by their nature, lack tight experimental controls.

Conclusion

Escalating health care costs, coupled with decreasing governmental economic resources, are reducing the availability of health care for underserved populations such as pregnant women.

TABLE 5—Cost and Outcome Data for Three Clinic Staffing Models

Productivity	67	0	101
Cost per kept appointment	27	18	0

Note. MDC = physician-based clinic; MSC = mixed-staffing clinic; RNC = nurse-based clinic.

This study found that increasing the availability of low-risk prenatal care professionals through the use of nonphysician maternal health providers, with physicians available for consultation, might substantially reduce the cost of providing this care while maintaining quality. Therefore, such a system might save valuable resources. The results have direct public policy implications for the staffing of low-risk prenatal care clinics. The findings regarding the mixed-staffing model underscore the importance of analyzing environmental issues such as clinic policies regarding individual patient appointments and lack of continuity of care. □

Medicaid Prenatal Care: A Comparison of Use and Outcomes in Fee-for-Service and Managed Care

James W. Krieger, MD, MPH, Frederick A. Connell, MD, MPH, and James P. LoGerfo, MD, MPH

ABSTRACT

Background. To control rising costs, state Medicaid agencies are enrolling recipients in managed care health plans (MCPs). We performed this study to assess this policy's impact on accessibility and outcomes of Medicaid-funded prenatal care.

Methods. We performed a retrospective, controlled study with three cohorts: a study group of 1106 Medicaid recipients enrolled in three MCPs, a matched comparison group of 4830 recipients receiving care in the fee-for-service (FFS) system, and a second matched comparison group of 4434 non-Medicaid enrollees of the same MCPs. Data on prenatal care use and birth outcomes were obtained through linkage of claims and discharge files with birth certificate files.

Results. Medicaid recipients enrolled in MCPs used prenatal care similarly to those in the FFS system and showed equal or modestly improved birth-weight distributions. However, Medicaid MCP enrollees showed poorer use of prenatal care and birth outcomes compared with non-Medicaid enrollees of the same plans.

Conclusions. Enrollment in MCPs has a neutral or small beneficial effect on the prenatal care received by the Medicaid population. However, providing financial access and modifying the system of care for this population did not result in parity with the general population. (*Am J Public Health.* 1992;82:185–190)

Introduction

Concern about access to health care, particularly among uninsured Americans, has been in the forefront of health policy discussions in recent years.[1–5] Diminishing access to prenatal care and a slowing of the rate of decline of infant mortality have focused attention on obstetrical care.[6,7] Numerous states have expanded their Medicaid programs in efforts to address these issues. In the early 1990s, Medicaid will cover approximately one quarter of all births.[8] This expansion of Medicaid will increase the already substantial costs of the program, rising at an annual rate of 6.2% since 1968 and now accounting for 36.4% of all state health spending.[9]

Many state Medicaid programs have initiated managed care systems in efforts to increase access while controlling costs. In these systems, the Medicaid agency contracts with a group of providers who deliver specified services to enrolled Medicaid recipients, generally in return for capitated payments.[10] Recipients may receive care only from participating providers. Medicaid managed care enrollment has increased from 187 340 in 1981 to 2 837 500 in 1991, and this growth is expected to continue.[9,11–14] Of those enrolled in managed care, 36% are health maintenance organization (HMO) members and 45% are in primary care case management fee-for-service programs. Approximately 11% of all Medicaid recipients are currently enrolled in managed care programs. Most of the enrollees are young women and children eligible through the Aid to Families with Dependent Children (AFDC) category, and obstetrical care accounts for a large proportion (33% to 41%) of Medicaid-AFDC expenditures.[15]

Available evidence indicates that Medicaid managed care may change use patterns and generate cost savings of 2% to 15% relative to fee-for-service care.[12,16–19] Less is known about the effects of managed care on accessibility and outcomes of care for Medicaid and low-income populations. Some observers have expressed concern that mandatory enrollment in designated health plans may jeopardize the quality of care received, while others suggest that managed care may improve access and continuity of care.[20–23] The Medicaid competition demonstration evaluation found no differences in the timing of initiation of prenatal care or in the distribution of birth weights between members of two mandatory enrollment managed care programs and the general AFDC population.[18] A recent study limited to Medicaid managed care members receiving care at one institution reached similar conclusions.[24]

In light of the likely continued expansion of Medicaid managed care and the large proportion of such care accounted for by maternity services, we performed this study of the impact of managed care on prenatal care for the Medicaid popula-

tion in Washington State. The study addresses two issues. First, does enrollment of pregnant Medicaid recipients in managed care plans result in different use and outcomes of prenatal care relative to Medicaid recipients receiving care in the fee-for-service system? Second, does managed care enrollment further the goal of promoting equity in prenatal care use and outcomes between Medicaid and non-Medicaid populations?

Methods

We conducted a retrospective, controlled study involving three cohorts: (1) women whose care was financed by Medicaid and provided by a managed care plan (the Medicaid managed care study group), (2) women whose care was financed by Medicaid and provided by the fee-for-service sector (the Medicaid fee-for-service comparison group), and (3) women whose care was financed by private enrollment payments and provided by a managed care plan (the non-Medicaid managed care comparison group).

Subject Selection

To select the two managed care groups, we used computerized discharge records to identify all women who delivered live infants between July 1983 and September 1988 while enrolled in three of the four managed care plans in Washington State that enrolled Medicaid recipients. (One of the four plans was unable to participate because of difficulties with its data system. One of the three participating plans declined to provide data on its non-Medicaid enrollees.) These records indicated the source of payment for each woman (Medicaid or non-Medicaid). To select the Medicaid fee-for-service group, we extracted from the Washington Medicaid Management Information System all hospital claims records of women who delivered live infants between February 1985 and January 1988 and who lived in counties in which the three managed care plans were operating. We excluded multiple births and stillbirths from all cohorts because of their distorting effects on birth weight.

We used data from both state Medicaid eligibility files and managed care plan enrollment files to characterize the system of care used by each individual during each month of pregnancy, that is, whether a woman (1) was enrolled in a managed care plan with either Medicaid or private financing, (2) was enrolled in fee-for-service Medicaid, or (3) had no identified system of care. Of the 1552 women identified from the managed care plans who had any months of Medicaid funding, 19% also had periods of private financing. To avoid misclassification, these women with mixed enrollment were excluded.

The length and timing of enrollment of each woman determines, in part, the degree of influence the source of care has on her pregnancy. Therefore, we determined the initiation and duration of each woman's enrollment in her system of care. Because nearly all (94%) women were continuously enrolled, we used the number of months enrolled to control for the degree of exposure to the system of care.

To control for local differences in Medicaid populations and for local variations in use of prenatal services, we frequency-matched by county of residence nine non-Medicaid managed care and nine Medicaid fee-for-service controls to each of the Medicaid managed care subjects in two plans. (For the remaining plan, no non-Medicaid managed care controls were available, and the limited number of available Medicaid fee-for-service controls permitted matching only one control for every two Medicaid managed care subjects. Overall, we were able to include approximately four controls for each case.)

Data Linkage

We used the Washington State birth certificate files as the source of dependent and confounding variables for all subjects. A computerized algorithm was created to find a unique birth certificate that matched each claim or discharge record. (Details of the linking process are available from the authors.) More than 90% of the claims and discharge records were linked with a unique birth certificate. We manually validated the accuracy of record linkages for all 1106 Medicaid managed care subjects and for a 10% random sample of the two comparison group subjects, and found 1.7% of the matches in error. The unlinked records did not differ significantly from the linked records with respect to maternal age, race, or enrollment history.

Analysis

We assessed the adequacy of the process of prenatal care with three indicators, each evaluating different aspects of care. To measure inadequate initiation of care, we computed the percentage of women whose care began in the third trimester or who received no care at all (late or no prenatal care).[25,26]

To measure the adequacy of use of care *once care was initiated,* we employed an expected visit index developed by Kotelchuck[27]: the ratio of the actual number of prenatal visits to an expected number, based on standards developed by the American College of Obstetricians and Gynecologists.[28] Use is inadequate if fewer than 50% of the expected visits occur.

Third, we computed a modification of the standard Kessner Index[29] that takes into account the current American College of Obstetricians and Gynecologists standards (available upon request). It establishes an optimal standard of care combining both initiation and use and does not adjust use for late initiation.

The outcome of prenatal care was measured by the percentage of low-birthweight (<2500 g) infants in each group.[25,30]

For univariate analyses, we tested for differences between proportions by calculating an odds ratio (OR) and its 95% confidence interval (CI).[31,32]

Because of the potential for selection bias (the Medicaid beneficiaries chose whether to receive care from fee-for-service or managed care providers), we controlled for factors other than source of care that may have affected the use of prenatal care and birth weight in two ways. First, as explained above, we frequency-matched by county. Second, we used multivariate logistic regression to control for potential confounding by age, race, smoking, parity, marital status, interbirth interval, prior preterm deliveries, and length of enrollment, as these have all been associated with the use of prenatal care and/or low birth weight.[25,33-38] We structured regression equations in a standard fashion.[39] In the final model, an OR was considered significantly different from one if its 95% CI did not include one.

Results

Medicaid Managed Care Compared with Medicaid Fee for Service

We first present the results of the comparison of Medicaid recipients enrolled in managed care plans and Medicaid recipients receiving care in the fee-for-service sector.

In general, the Medicaid beneficiaries in the managed care and fee-for-service systems of care were similar with respect to age, months of enrollment in Medicaid, race, marital status, smoking, parity, and prior preterm deliveries. They differed in that the Medicaid fee-for-ser-

vice group had a significantly shorter average interbirth interval than the managed care cohort (Table 1). Shorter interbirth intervals are associated with lower birthweight infants, but only when less than 18 months.[37] The managed care members enrolled in their system of care later than those in the fee-for-service cohort: 25.3% of the former enrolled in the third trimester compared with 15.2% of the latter ($P < .001$).

Differences in the use and outcomes of prenatal care between the managed care and fee-for-service groups varied among the three managed care plans. Therefore, we analyzed the data stratified by plan and cannot present aggregate results for all managed care plans. All ORs in Table 2 express the risk of inadequate care in the managed care group relative to the fee-for-service group. Adjustment for months of enrollment, maternal age, and maternal race did not greatly change these ORs. Also, additional adjustment for marital status, parity, smoking, number of prior preterm pregnancies, and interbirth interval did not further change the ORs.

Two of the managed care plans had fewer women with late or no prenatal care relative to fee-for-service care (only one significantly so). Members of the remaining plan received significantly later care than their fee-for-service counterparts. This finding did not change when we confined the analysis to the subset of women who were enrolled for all 9 months of pregnancy (38% of the total sample of Medicaid subjects). Any impact of the source of care would be most unambiguously demonstrated in this group.

For all three plans, we found no important or significant differences in the expected visit index between women in the managed care and fee-for-service systems. Thus, once a woman initiated care, it appeared that she received a similar number of visits in both systems (Table 2). In the subset of women enrolled for 9 months, a nonsignificant trend showing fewer women with inadequate numbers of visits in the managed care system emerged (adjusted ORs ranged from 0.41 to 1.00).

The modified Kessner Index indicated that two managed care plans had fewer women with overall inadequate care (one significantly so), while the remaining plan had significantly more (Table 2). Restricting the analysis to those women enrolled for all 9 months of pregnancy did not substantially alter these results.

Two of the managed care plans showed improved outcomes, as measured by the proportion of low-birth-weight infants (one significantly so). The remaining plan showed a nonsignificant trend toward poorer outcomes (Table 2). Restricting the analysis to those women enrolled for all 9 months of pregnancy did not importantly alter these results.

TABLE 1—Description of Study Groups by Source of Care

*$P < .001$. ***$P < .01$.
**$P < .005$. ****$P < .05$.

Medicaid Managed Care Compared with Non-Medicaid Managed Care

We next examined whether differences existed in the use and outcomes of prenatal care between Medicaid and non-Medicaid enrollees of managed care plans.

Members of the Medicaid group differed notably from the non-Medicaid managed care plan members. The Medicaid group was younger, had enrolled in care for fewer months of pregnancy, and had a higher prevalence of smokers, single mothers, non-Whites, prior pregnancies, and prior preterm pregnancies. While 25.3% of Medicaid managed care members enrolled during the last trimester of pregnancy, only 2.3% of the non-Medicaid members did so ($P < .001$).

Medicaid beneficiaries showed significantly poorer indices of use and birth outcomes than non-Medicaid enrollees. We present aggregated data from two plans because interaction between plan and source of care was not significant. As the remaining plan did not provide data on its non-Medicaid enrollees, it is not included in this analysis.

Medicaid enrollees experienced significantly higher rates of late or no prenatal care, an inadequate visit index, inadequate overall care as measured by the modified Kessner Index, and low-birthweight infants. In Table 3, the ORs indicate the risk of poor-quality care among Medicaid enrollees relative to non-Medicaid enrollees.

The unadjusted ORs reflect the experience of the Medicaid population (which is younger and has a higher proportion of Black and single mothers) relative to the non-Medicaid group. This is the appropriate measure to use when examining whether managed care can compensate for these risk factors of poor access and outcomes and actually bring the Medicaid group to the same level as the non-Medicaid group. The managed care plans were unable to do so.

The adjusted ORs address the question of whether there were differences in use and outcomes if the two groups had equivalent risk factors (age, race, marital status). After adjustment, Medicaid members continued to receive inadequate care at higher rates but no longer differed significantly in the proportion of low-birthweight infants.

Additional adjustment for plan, parity, interpregnancy interval, prior preterm births, and smoking did not cause further changes in the ORs.

Discussion

Enrollment of Medicaid beneficiaries in three managed care plans in Washington State was, on balance, associated with equal use of prenatal care relative to that of women served by the fee-for-service

TABLE 2—Medicaid Managed Care (MMC) vs Medicaid Fee for Service (FFS): Risk of Inadequate Prenatal Care and Low Birth Weight by Plan

sector and equal or modestly improved rates of low birth weight. These findings are consistent with those of previous studies.[18,24] In light of the data showing modest cost savings associated with managed care enrollment,[12,16–19] this policy appears promising. However, any attempt to generalize about the potential of managed care to improve birth outcomes and access to prenatal care must be tempered by the recognition that its impact differed within each of the managed care plans. Medicaid managers must carefully consider each plan in which they enroll recipients and monitor quality of care on a continuous basis.

Enrollment of the Medicaid beneficiaries in "mainstream" managed care did not eliminate the large gap in prenatal care use and birth outcomes between the Medicaid population and the general population of managed care enrollees. More Medicaid enrollees delivered low-birth-weight infants and more had inadequate access to prenatal care than general plan members. Even after adjusting for several risk factors, Medicaid members showed poorer use of care. Simply ensuring the availability of providers or extending eligibility is not sufficient to equalize the rates of adequate prenatal care use and good birth outcomes between the Medicaid and non-Medicaid populations.[18,40] The structure and content of the care offered by providers seems critical in promoting improved outcomes.

Our data demonstrated late enrollment in Medicaid by pregnant women regardless of system of care. This suggests that additional efforts are needed to facilitate earlier enrollment, such as improvement of the capacity of the maternity care system, public education, case finding, and enhanced social support services.[26]

We noted generally equal numbers of prenatal visits among Medicaid managed care and fee-for-service users once care was initiated, as reflected in the expected visit index. This finding agrees with several studies that found equal use of ambulatory services (not specifically prenatal care) among Medicaid beneficiaries in managed care and fee-for-service systems of care[17,41,42] while differing from others showing decreased[19,43,44] or increased[16] use of outpatient services in managed care systems. Several studies of non-Medicaid populations have compared the quality of maternity care received by HMO members relative to fee-for-service users. Their results are consistent with our findings of equal or better care in the managed care setting.[45–52]

There was not a consistent association of earlier initiation of prenatal care and lower rates of low birth weight. Among members of plan 1, while more women in the Medicaid managed care group had late or no prenatal care, they

also had fewer low-birth-weight infants than their fee-for-service counterparts. Medicaid recipients enrolled in plan 2 showed no significant differences in initiation of care and low-birth-weight rates relative to their fee-for-service counterparts. Recipients in plan 3 had improved timing of initiation of care (with borderline statistical significance) but equal rates of low birth weight.

These findings may be explained by noting that the association between prenatal care and birth outcomes is best studied with the individual as the unit of analysis, rather than the group. Consistent with this hypothesis is the study by Quick et al.[51] that found that members of the Kaiser-Permanente HMO in Oregon started care significantly later and received fewer visits but had modestly heavier infants relative to the general population. Despite this inverse relationship between use and outcomes, Quick et al. found an overall association of prenatal care with heavier infants in their study population when using the individual as the unit of analysis. This may reflect a "start-up" phenomenon among new users of managed care in which delays occur in establishing contact with a primary provider because of the more complex organizational structure of managed care plans. Or perhaps the women who chose managed care plans had other associated characteristics that were related to lower use of prenatal care yet better birth outcomes.

The most important caveat in interpreting the results of this study is that we were probably unable to control completely for the confounding introduced by selection bias. The potential for confounding by selection bias was strongest in the comparison of the Medicaid managed care and fee-for-service cohorts. However, eligibility for Medicaid in itself ensures a great deal of economic and social homogeneity. Additionally, we were able to control for the potential confounding effects of many covariates using available data from the birth certificates. The characteristics of the two Medicaid groups (Table 1) offer some evidence that the two cohorts are, in fact, similar.

Although several authors have questioned the reliability of some elements of birth certificate data,[25,29,53] the data we used in this study appear to be reasonably accurate. P. Starzyck (personal communication, August 1989) compared information from birth certificates with data in medical records for 765 births taking place in Washington State. The certificate and record disagreed in 3.4% of entries for birth weight, 4.2% for month of initiation, and 9.3% for number of visits. Furthermore, we had no reason to suspect a differential miscoding or error rate in one of our study groups relative to the others.

Failure to link all claims to birth certificates might have introduced ascertainment bias into this study. We fell short (by less than 10%) of linking all claims and discharge records to birth certificates. Because the linkage rates were similar among the different sources of care, introduction of bias was unlikely.

Our sample sizes for some comparisons were smaller than we had anticipated, primarily because the necessity of conducting a stratified analysis prevented us from pooling the data from the three plans. The small sample sizes in the stratified analysis raise the possibility that the lack of differences between some managed care and fee-for-service providers for some dependent variables may have been due to a type II error. For most comparisons, our sample size was large enough to detect a 50% difference between fee for service and managed care but too small to find reliably a significant difference of 25% when setting α equal to 0.05 and β equal to 0.80. The comparison of Medicaid managed care enrollees and their non-Medicaid counterparts used a larger sample (pooled across plans) and detected significant differences in most of the dependent variables.

In conclusion, managed care may offer an opportunity for modest cost savings while promoting modest improvements in prenatal care, or at least doing no harm. However, managed care alone will not substantially narrow the differences in prenatal care access and birth outcomes between the Medicaid and general populations. Facilitating earlier enrollment in Medicaid programs may increase the proportion of low-income women with timely initiation of prenatal care. Designing prenatal care programs whose content addresses the specific needs of Medicaid beneficiaries may also narrow the gap. □

Acknowledgments

This research was supported in part by the Robert Wood Johnson Foundation Clinical Scholars Program and a grant from the Bureau of Maternal and Child Health and Resources Development (MCJ 9043).

This paper was presented in part at the annual meeting of the Association for Health Services Research, June 1989.

Attitudes about Infertility Interventions among Fertile and Infertile Couples

L. Jill Halman, RN, PhD, Antonia Abbey, PhD, and Frank M. Andrews, PhD

ABSTRACT

Background. There has been marked progress in the development of infertility interventions. This paper reports attitudes about 11 interventions for infertility.

Methods. Face-to-face interviews were conducted with each member of 185 infertile and 90 presumed fertile couples in southeastern Michigan.

Results. Seven of these interventions were generally viewed favorably and four were generally viewed negatively, regardless of the couple's fertility status. Infertile couples viewed all interventions, except for adoption, more favorably than did fertile couples. Multidimensional scaling was used to cluster the interventions according to similarity in endorsement. These clusters form a continuum from interventions that allow only one member of the couple to be a biological parent to the most noninvasive techniques. All clusters remain roughly equidistant from adoption, in which neither member of the couple is a biological parent.

Conclusions. Interventions that produce a child who is biologically related to only one member of the couple were viewed most negatively. Members of couples who were receiving fertility treatment made finer discriminations among infertility interventions than did individuals who had not received treatment. (*Am J Public Health.* 1992;82:191–194)

Introduction

Over the last 40 years, there has been marked progress in the development of interventions available to couples having fertility problems. This progress has been followed by criticism and debate concerning the moral and ethical issues involved in the use of these interventions. As early as 1951, infertility interventions were the subject of debate. The use of artificial insemination with donor's sperm was criticized at that time for its possible negative effects on the husband's ability to properly raise and care for the resultant child.[1] With the board certification of infertility specialists in 1973, increased research resulted in the availability of more highly technical and varied interventions.[2] These techniques and their acronyms, such as in vitro fertilization (IVF) and gamete intrafallopian transfer (GIFT), are making their way into everyday conversation; their appropriateness, acceptability, and ethical implications are being discussed and debated by many individuals, organizations, and religious groups.

Little empirical research has been conducted to explore what the public thinks about the interventions available today and how acceptable these interventions are to them. This paper reports such data. Our findings should have relevance for those health professionals involved in treating and working with people with fertility problems.

Methods

In this cross-sectional study, married couples were asked their attitudes about 11 infertility interventions. Both husbands and wives in 275 couples in southeastern Michigan were interviewed in 1988. One hundred eighty-five couples recognized that they had a fertility problem and were actively trying to solve it. One hundred sixty-one of these couples were recruited from nominations made by infertility specialists. Nine couples were volunteers from support groups (i.e., RESOLVE and the Endometriosis Association), and a few were marriage license applicants, volunteers recruited through newspaper advertisements, and other study participants. Ninety presumed fertile couples were interviewed. Forty-two were recruited by nominations made by infertility specialists who had presumed fertile gynecologic patients within their practices and by nominations made by obstetricians/gynecologists; 33 were recruited from marriage license applicants; and a few couples were volunteers recruited through newspaper advertisements and other study participants.

All study participants met the criteria of being married, White, and middle class,* and having no previous children by either member of the couple. Infertile cou-

*Middle class was defined as having at least a high school education and an annual family income in the approximate range of $20 000 to $100 000. Our respondents had an average education of 2.5 years of college and an average family income of $45 000.

***$P \leq .01$.

ples met the additional criteria of having seen an infertility specialist, feeling they were having a difficult time having a baby, and not yet having completed the most advanced infertility treatments (e.g., IVF). Although our study originally used trying to have a child for 12 months or longer as a criterion to define fertility problems, we found that several couples had already sought treatment from infertility specialists before 12 months had elapsed. For the purposes of this data analysis, it was believed that couples who had already been involved in discussions and decision making with their physicians about infertility interventions should be included with the other infertile couples to give a more accurate picture of attitudes about infertility interventions among couples presented with this problem. Presumed fertile couples met the additional criteria of the wife's having a regular menstrual cycle and having no known gynecological problem that would affect the couple's fertility status. Eighty one percent of the referred and eligible couples participated in this study.

One-hour face-to-face interviews were conducted separately with each member of the couple.

Individual members of couples were asked, "People have different opinions about various methods for having a child. Please tell me how you feel about the possibility of *your* using each of the following methods, *if it were needed. . . .*" The 11 infertility interventions measured include artificial insemination with the husband's sperm (AIH), artificial insemination with a donor's sperm (AID), artificial insemination using both the husband's and a donor's sperm mixed together (AIH&D), hormones used to stimulate ovulation in women, hormones used to increase the sperm count in men, progesterone (a specific hormone) vaginal suppositories used to prevent miscarriage, tying the cervix to prevent miscarriage, in vitro fertilization (IVF), adoption, surrogate mother with husband-donated sperm and wife-donated ova (S/W), and surrogate mother with husband-donated sperm and the surrogate's ovum (S/S). Attitudes were measured on 5-point Likert-type scales, with options ranging from strongly opposed to personal use of a particular intervention (1) to strongly in favor of personal use of a particular method (5).

Results

In this study we examined the interventions and procedures that the fertility-problem couples had received at the time of the interview. The most frequent intervention used for women was the prescription of medications to stimulate ovulation. Adoption was currently being or had previously been considered by 20% of all fertility-problem couples and was the most commonly mentioned intervention by men. Endometriosis was a relatively common problem for the female respondents: 19% stated that they had had or were scheduled to have surgery for it and 14% stated that they had taken or were receiving medication for it. The second most common intervention reported by men was artificial insemination with the husband's sperm. Twenty percent of the men stated that they had used or were currently using this intervention.

Attitudes about Interventions

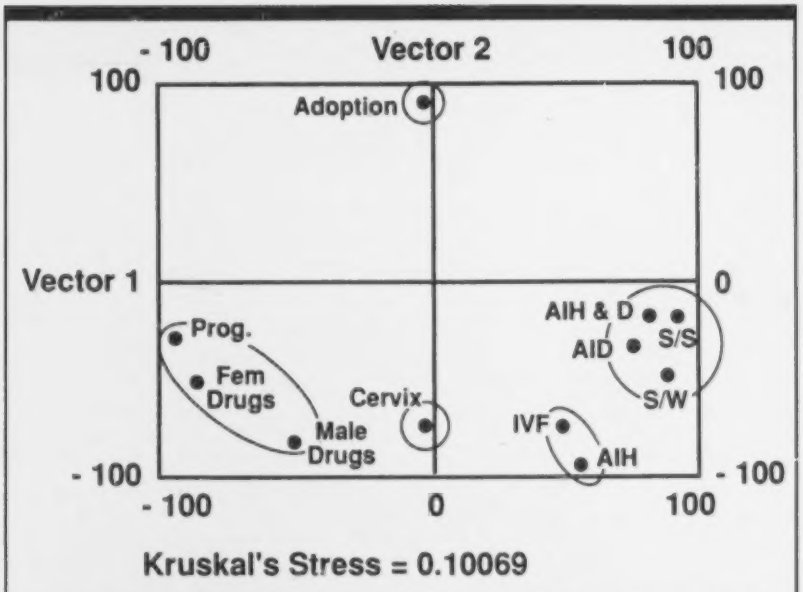
Table 1 contains respondents' attitudes about the various fertility interventions. It shows that S/S, S/W, AID, and AIH&D were viewed the most unfavorably by both fertile and infertile couples. It is noteworthy that most of these interventions allow only one member of the couple to be a known biological parent of the child. Although a couple using S/W would be known biological parents, the fetus would be carried by another woman. The remaining seven interventions are generally viewed favorably by both sets of couples. The lower acceptability of IVF among the acceptable interventions may

be due to the newness of this intervention or to the high cost, which is generally not covered by third-party payors. Infertile couples were more favorable toward all interventions, except for adoption, than were fertile couples. The Student t test shows a significant ($P \leq .01$) difference between the infertile couples' mean scores and the fertile couples' mean scores, except for IVF, AIH&D, S/W, and S/S. Adoption was the most acceptable alternative for fertile couples, whereas it was seventh for infertile couples.

As can be seen in Table 1, infertile wives and husbands showed the same hierarchical ranking of acceptability of infertility interventions, although the wives were generally more favorable toward the use of interventions. Fertile husbands and wives generally showed agreement within couples for acceptability of infertility interventions, except for male hormones, AID, S/W and S/S.

Figure 1 shows the structure of infertile couples' attitudes about 11 infertility interventions. These results were generated by applying multidimensional scaling to a matrix of correlation coefficients that reflect similarities of endorsements. In the figure, small distances between interventions imply high similarity in patterns of endorsement, and large distances imply low similarity (i.e., independence) in patterns of endorsement.** As can be seen in Figure 1, infertile couples show five clusters according to similarity of endorsement: (1) interventions in which only one member of the couple is a known biological parent, or another person is involved (S/S, S/W, AID, and AIH&D); (2) IVF and artificial insemination with husband's sperm (AIH); (3) temporary tying of the cervix to prevent miscarriage; (4) hormone medications; and (5) adoption.

Figure 2 shows multidimensional scaling results for fertile couples. Fertile couples showed less discrimination among the 11 techniques than the infertile couples did, with three clusters being depicted: (1) interventions in which only one member of the couple is a known biological parent, or another person is involved (S/S, S/W, AID, and AIH&D); (2) adoption, and (3) the remaining six interventions. All interventions, for both the infertile and fertile couples, are about equidistant from adoption. By comparing the results shown in Figures 1 and 2 with those in Table 1, we can see that 10 interventions also approximate a continuum across the diagram, moving from interventions viewed more negatively to those viewed more favorably.



AID = artificial insemination with donor's sperm; AIH = artificial insemination with husband's sperm; AIH&D = artificial insemination with husband's and donor's sperm mixed; Cervix = tying cervix to prevent miscarriage; Fem Drugs = drugs used to stimulate ovulation; IVF = in vitro fertilization; Male Drugs = drugs used to increase the sperm count; Prog = progesterone vaginal suppositories to prevent miscarriage; S/S = surrogacy using surrogate's ovum and husband's sperm; S/W = surrogacy using wife's ova and husband's sperm.

FIGURE 1—Interventions for infertile couples, multidimensional scaling.

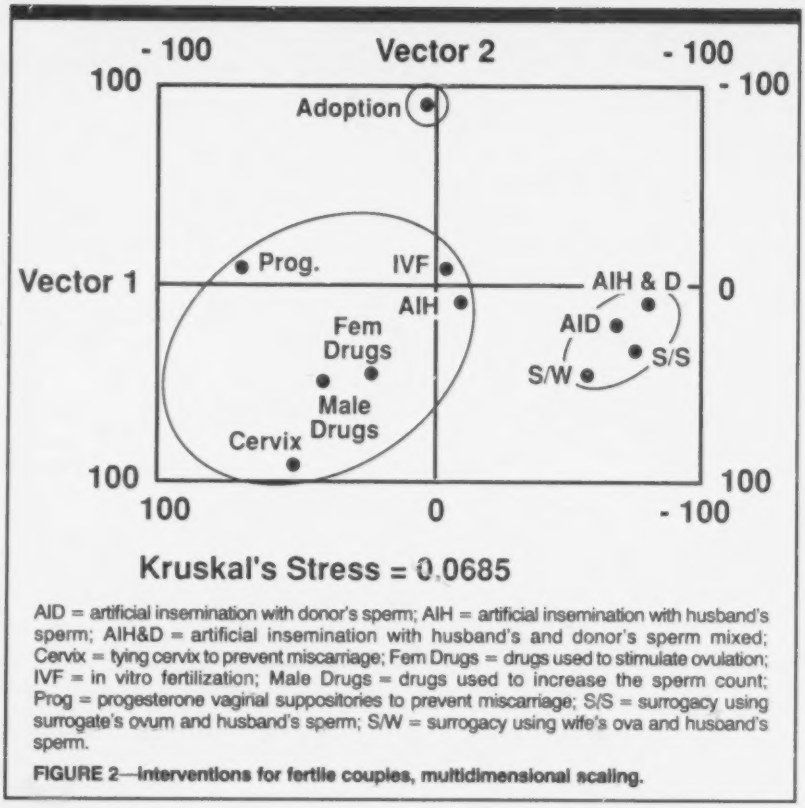
Discussion

Comparing the frequency of the procedures and interventions used among the infertile couples with the acceptability of various infertility interventions, we can see that, in the aggregate, couples are using interventions that are generally the most acceptable to them. Adoption is the one intervention that is inconsistent with this. Although adoption was frequently pursued by infertile couples, it was the least acceptable of the interventions that infertile couples felt they could use. This result may have been influenced by the respondents who participated in this study. Couples who strongly prefer to be the biological parents of their child may be the couples who seek treatment from an infertility specialist (our primary source of referral for infertile couples). Although the couples in this study may have proceeded with investigation of adoption to assure themselves of success in eventually having a child, they may not yet have been ready to accept this as their ultimate intervention.

Comparing infertile couples to fertile couples, we see that the infertile couples viewed all interventions, except for adoption, more favorably than did the fertile couples. The explanation for this may be the same as stated in the previous paragraph, but a different explanation is also possible. Some couples in our pretest who adopted after receiving infertility treatment spoke about not seriously considering adoption as an intervention initially because they had not considered it an alternative treatment. It is known that surprise and shock are among the first emotions felt by couples when they suspect they may be infertile.[3,4] It may be that knowledge of infertility comes as such a surprise to some people that they do not recognize all the options available to them and instead focus only on seeing an infertility specialist.

Both fertile and infertile couples viewed interventions in which only one member of the couple is a biological parent the most negatively. This attitude may be explained by members of the couple

**To select the appropriate dimensional solution, one should assess how well the configuration approximates the actual data. This can be measured by Kruskal's stress coefficient, which is .10 and .07 (i.e., "fair" to "good") for the two-dimensional solutions of Figures 1 and 2, respectively.



AID = artificial insemination with donor's sperm; AIH = artificial insemination with husband's sperm; AIH&D = artificial insemination with husband's and donor's sperm mixed; Cervix = tying cervix to prevent miscarriage; Fem Drugs = drugs used to stimulate ovulation; IVF = in vitro fertilization; Male Drugs = drugs used to increase the sperm count; Prog = progesterone vaginal suppositories to prevent miscarriage; S/S = surrogacy using surrogate's ovum and husband's sperm; S/W = surrogacy using wife's ova and husoand's sperm.

FIGURE 2—Interventions for fertile couples, multidimensional scaling.

preferring equity in relation to the child; that is, if both parents are unable to have a child biologically, then perhaps it is better to have neither be a biological parent and to adopt a child instead.

The multidimensional scaling shows that within their clusters, infertility interventions seem to follow a continuum from those that allow only one member of the couple to be a known biological parent to those that allow both spouses to be biological parents. These 10 interventions are roughly equidistant from adoption, presumably because neither member of the couple would be a biological parent with that intervention.

Future research is necessary to determine the extent to which the pattern of attitudes found here is representative of that in the general population. These findings have implications for health care providers regarding the reluctance that couples experiencing fertility problems may have, at least initially, to accept some interventions required for the couple to conceive. These findings could serve as a general guide for ease of acceptance of certain interventions and for the degree of emotional support some couples may require in order to make an informed decision about the use of a particular technique. Couples may benefit by having the alternative of adoption addressed and given legitimacy as an acceptable intervention from the onset of infertility treatment. The finding that infertile couples had more favorable attitudes than did fertile couples toward various interventions suggests that when couples are confronted with more information and personal necessity, their attitudes about infertility interventions become more positive. □

Acknowledgments

This work was sponsored by NICHD (grant HD21240).

We would like to express our appreciation to the physicians and nurses who took the time from their busy practices to facilitate the referral of respondents for this study. We are especially appreciative of the couples who so graciously and willingly participated in this project; without their cooperation this study would not have been possible.

A portion of these results was presented at the 1989 annual meeting of the American Psychological Association, New Orleans, La.

Nonclinical Factors Associated with Surgery Received for Treatment of Early-Stage Breast Cancer

ABSTRACT

Background. Women diagnosed with early breast cancer have had the opportunity to receive breast-conserving surgical treatment, which reduces the physical and psychological morbidity heretofore associated with breast removal.

Methods. Nonclinical factors associated with women receiving partial mastectomies with radiation (P+R) compared with modified radical mastectomies without radiation (MOR) were examined in 2238 Black and White women diagnosed, in 1985 through 1987, with early-stage breast cancer in the metropolitan Detroit area.

Results. Age at diagnosis and size of hospital were the strongest predictors of type of surgery received, with younger women (less than 55 years of age) and women treated in larger hospitals (more than 500 beds) more than twice as likely to receive P+R. Stratifying on race, age at diagnosis remained the strongest predictor for White women, followed by hospital size. Among Black women, hospital size was more strongly associated with surgery received than was age.

Conclusions. Younger women and women undergoing treatment at large hospitals are more likely to receive the breast-conserving P+R. Black women treated in small hospitals appear to be particularly unlikely to receive P+R. (*Am J Public Health.* 1992;82:195–198)

Introduction

Breast cancer is the most common malignancy in women. It is estimated that 150 000 new cases are diagnosed each year in the United States.[1] Surgery remains the standard form of treatment, with over 90% of all cases receiving some surgical intervention.

The breast-sparing partial mastectomy has gained credibility in the treatment of early-stage breast cancer with the publication of the results of several randomized clinical trials undertaken in the 1970s and 1980s.[2–4] These studies demonstrated no significant difference in the duration of survival between women receiving either partial mastectomies with radiation or modified radical mastectomies without radiation for early-stage disease. With nearly 50% of all breast cancers being diagnosed at a localized stage,[5] there are clearly a substantial number of women for whom the less invasive procedure may be an option. The potential impact on the psychological and physical morbidity heretofore associated with breast removal[6,7] also is important. Laws have been enacted in a number of states requiring physicians to inform breast cancer patients of treatment alternatives. Although there has been an increase in the proportion of cases receiving partial mastectomies since 1980, the procedure has not become the standard surgical treatment for women with early-stage disease. In this report, we use data from a population-based cancer registry encompassing the racially and socioeconomically diverse, urban population of the Detroit metropolitan area to identify nonclinical factors associated with women receiving partial mastectomies with radiation compared with modified radical mastectomies without radiation in a sample of breast cancer patients with similar clinical profiles.

Methods

Cases were selected for this study who met the criteria for breast-sparing treatment.[4] The study includes 2238 Black and White women diagnosed, in 1985 through 1987, with microscopically confirmed, node-negative, incident invasive cancers of the breast less than or equal to 3.9 cm who received either partial mastectomies with radiation (P+R) or modified radical mastectomies without radiation (MOR) as the first course of treatment. More than 90% of all first primary breast cancers diagnosed during this time period in the metropolitan Detroit area were treated with one of these modalities. Cases were identified through the Metropolitan Detroit Cancer Surveillance System (MDCSS), a participant in the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) program.[5] The MDCSS encompasses a population of 4.1 million residents of the metropolitan Detroit tricounty area. Medical and demographic information is obtained for incident cancer cases from all

tricounty facilities that provide care for cancer patients as well as three out-of-area hospitals that provide treatment for approximately 10% of cancer patients from the surveillance area. The MDCSS is considered to have complete registration of area cancer cases, with 1.2% of the cases identified by death certificate only.

Nonclinical factors included age at diagnosis, race, marital status, year of diagnosis, size of the hospital where a patient's surgery was performed, and total number of breast cancer surgeries performed by a patient's surgeon during 1985 through 1987. Odds ratios (ORs) were calculated as a measure of association between the nonclinical factors and treatment. Stepwise logistic regression with BMDP[8] was employed to fit the data using all variables. The significance of each term was assessed by the F test. The population-attributable fraction was calculated to determine the proportion of breast-conserving treatment accounted for by the variables that were associated with this treatment.[9]

Results

Of the 2238 women included in this study, 657 (29.4%) received P+R and 1581 (70.6%) received MOR for treatment of early-stage breast cancer (Table 1). Although women 55 years of age or older account for almost 70% of the cases, proportionately fewer of them received P+R (23.6%) compared with women less than 55 (42.4%). Black women account for 13.6% of the study population. They did not differ from White women in treatment received. More women underwent surgical treatment (55.8%) in smaller hospitals (maximum of 500 beds), but they were less likely to receive P+R in these hospitals (Table 1). A majority of the women in this study (65.9%) were treated by surgeons who had performed 50 or fewer breast cancer surgeries during 1985 through 1987, yet fewer of them received P+R than those treated by surgeons who had performed more than 50 surgeries (Table 1).

The logistic regression analysis (Table 2) indicates that, controlling for the other variables, type of surgery received for early-stage breast cancer is associated with the following factors: age at diagnosis, size of hospital, and number of surgeries performed by a patient's surgeon. Younger women are more than twice as likely as older women to receive P+R (OR = 2.38; 95% confidence interval [CI] = 1.96, 3.03). Women undergoing surgery at larger institutions are twice as likely to receive P+R as women at smaller hospitals (OR = 2.13; 95% CI = 1.73, 2.62). Women treated by surgeons performing more than 50 breast cancer surgeries in the study period were slightly more likely to receive P+R than women treated by surgeons performing 50 or fewer (OR = 1.28; 95% CI = 1.03, 1.58). No significant interaction is apparent for hospital size and age at diagnosis, number of surgeries and age at diagnosis, or number of surgeries and hospital size (data not shown). On the basis of the population-attributable fraction, about 15% of the breast-conserving treatment is explained

by age at diagnosis, 16% by hospital size, and 3% by number of surgeries performed.

Since the association between specific nonclinical characteristics and treatment might not be similar for Black and White women, we stratified on race (Table 3). Age at diagnosis and hospital size remain significant for both Black and White women. Also, year of diagnosis is significant.

Age at diagnosis remains the strongest predictor for White women, while for Black women hospital size is the strongest predictor of breast-sparing treatment (Table 3). Year of diagnosis is more predictive of treatment type than the number of surgeries performed by a woman's physician for both Black and White women when the two racial groups are considered separately. The associations, however, are in the opposite direction (Table 3). This may account for the lack of year effect in the model when Blacks and Whites were pooled. A χ^2 test for trend was significant within each racial group but was stronger for White women (10.93; $P < .005$) than for Black women (4.11; $P < .05$).

Discussion

Overall, a younger woman is considerably more likely to receive P+R for treatment of early-stage breast cancer than is her older counterpart presenting with the same breast cancer. Although it has been shown in other studies[10–12] that older women typically receive less invasive (i.e., less definitive) therapy than younger women, in this study older women were less likely to receive the partial mastectomy. There are a number of possible explanations for this seeming contradiction in the age-related treatment patterns for breast cancer. Standard therapy requires that partial mastectomy be accompanied by radiation treatment. Six weeks of radiation therapy may be contraindicated by comorbid conditions or the physical status of an older woman. Physicians may be less likely to recommend this treatment for their older patients regardless of their physical status. Although many of the patients in this study would have received information on treatment options from their physicians as mandated by Michigan's breast cancer informed-consent legislation,[13] it is not known how objectively this information is presented. Older women may be more sensitive to their physician's opinions and recommendations, and thus more likely to defer to their doctor. In contrast, younger women may be more likely to read materials presented to them, to question the physician, and to take a more active role in the treatment decision-making process. Physicians may be more likely to recommend a breast-sparing technique to a younger woman, bringing in their own attitudes about "femininity" and the age relatedness of the importance of breast conservation.

The finding that women are more likely to receive P+R at a large hospital suggests that new treatment modalities may be implemented more quickly in environments associated with medical centers, research programs, and physician training, which are usually located in larger institutions. Black and White women in this metropolitan area who receive treatment at large institutions are going to the same large institutions and do not differ in their overall probability of receiving P+R compared with MOR. Black women being treated for early-stage breast cancer are less likely to receive P+R at smaller hospitals than White women being treated in hospitals of the same size. White women receiving treatment at smaller institutions are more likely to be seen in suburban hospitals, while Black women are more often seen in urban hospitals. Thus, the treatment differences in the small hospitals are urban–suburban variations. Further studies should investigate whether Black women seen in small hospitals do not receive P+R as often because their physicians are concerned about treatment compliance for the radiation component, because radiation therapy is not available at those hospitals, or because these women are not provided with adequate information about alternative treatments.

The years included in this study are those immediately following the publication of data that demonstrated no significant survival differences between women receiving P+R and MOR for treatment of early-stage breast cancer. These data have been reinforced recently with the publication of data showing similar results after 8 years of follow-up.[14] Women have the opportunity to receive a breast-conserving surgical treatment that eliminates the physical and psychological morbidity heretofore associated with breast removal. The results of this study indicate that younger women and women undergoing treatment at large hospitals are more likely to receive breast-preserving treatment. Black women being treated in small hospitals appear to be particularly unlikely to receive P+R. The time trend among White women shows a decline in the proportion receiving P+R in both 1986 and 1987, compared with 1985. This trend should be observed for the next 2 to 3 years and studied in depth if it continues. Furthermore, since no single variable considered in this study explains more than 16% of the shift toward breast-con-

serving therapy, future studies must include other factors that are likely to influence treatment decisions. Consideration should be given to comorbid conditions, factors that influence a woman's decision to undergo one form of treatment compared with another for early-stage breast cancer, information provided to women about treatment options, and physician characteristics associated with use of breast-conserving treatment. □

Epidemiology Summer Program to Be Held at Tufts University

The New England Epidemiology Institute and Tufts University will sponsor a 3-week summer program in epidemiology at Tufts' Medford campus July 12 to 31, 1992. The program includes both methodologic and substantive courses intended for those seeking an introduction to modern epidemiologic concepts as well as those desiring a review of recent developments in epidemiologic thinking.

Fourteen courses will be offered, including Theory & Practice of Epidemiology (introductory and advanced levels), Causal Inference, Biostatistics for Epidemiologists, Regression and Categorical Data Methods, Logistic Regression and Survival Analysis, Conducting Epidemiologic Research, The Biology and Epidemiology of Cancer, Environmental Epidemiology, Nutritional Epidemiology, Clinical Epidemiology, Concepts of Infectious Disease Epidemiology, Perinatal Epidemiology, and Epidemiology in Public Health Practice. Invited faculty include excellent teachers and prominent researchers from leading universities. Registrants may receive graduate degree credit or continuing education credit, Continuing Medical Education credit (AMA Category 1), or Certification Maintenance credits in industrial hygiene.

For more information please contact The New England Epidemiology Institute, Dept. 15, One Newton Executive Park, Newton Lower Falls, MA 02162. (Phone: 617/244-1200; FAX: 617/244-9669.)

Breast Cancer Screening Practices among Users of County-Funded Health Centers vs Women in the Entire Community

ABSTRACT

Background. Breast cancer screening rates tend to be lower among women with lower income and/or education.

Methods. Telephone surveys of random samples of women aged 50 to 75 who had visited five health centers (n = 795) and women in the same age group residing in the entire community (n = 404) were conducted in 1988.

Results. Despite the significantly lower socioeconomic level, a higher proportion of minority women, and a poorer knowledge of mammography, screening rates in the health center group were not lower than in the community sample. About half or more of the health center respondents had ever had a mammogram regardless of income, education, age, and ethnic group. Of the community respondents, 49% had ever had a mammogram, but the proportion varied significantly by income and education. Within the subgroup of women having annual incomes below $15 000, mammography use was actually higher among health center women; that is, 50% of health center vs 35% of community women reported ever having a mammogram and 31% vs 14%, respectively, reported having a mammogram in the past year.

Conclusion. The findings demonstrate the importance of publicly funded health centers in achieving screening rates among the socioeconomically disadvantaged that are comparable to (or even higher than) those in the general population. (*Am J Public Health.* 1992;82:199–203)

Dorothy S. Lane, MD, MPH, Anthony P. Polednak, PhD, and Mary Ann Burg, PhD, MSW

Introduction

In 1989 the National Cancer Institute (NCI) released a consensus statement about guidelines for mammography screening that was endorsed by 11 national organizations, including the American Cancer Society (ACS) and the American Medical Association. This statement includes a recommendation for annual mammography and breast examination for women aged 50 and older.[1] The *Guide to Clinical Preventive Services,* by the US Prevention Services Task Force, also recommends that women aged 50 to 75 have a breast examination annually and mammography annually or every 2 years.[2] And in *Healthy People: 2000* (1990), the US Department of Health and Human Services set a national goal to increase to at least 60% the proportion of women aged 50 and older who have received a clinical breast examination and a mammogram in the preceding 1 to 2 years (and to increase to at least 80% the proportion who have ever received them).[3]

Preventive health services are traditionally underused, particularly by the poor, who have competing and more urgent priorities as well as greater problems of access to all health services. And although mammography is a highly effective screening technology for breast cancer, it is not adequately used, particularly by low-income women.[3,4] Yet, despite the higher incidence of breast cancer among women of higher socioeconomic status,[5] the need for early detection of breast cancer is most evident among the socioeconomically disadvantaged because they suffer higher mortality due to later-stage diagnosis.

This paper assesses differences in breast cancer screening practices between samples of predominantly low-income women aged 50 to 75 using county-funded health centers and a population-based sample of women in the same age group residing in the towns where the health centers are located.

Methods

Background

This study was part of an NCI-supported project to increase the use of mammography and physical breast examination on a communitywide basis among women 50 years of age and older through public and physician education, as described in detail elsewhere.[6] Baseline surveys were done for needs assessment related to planning interventions to improve the use of mammography and physical breast exam, as well as to contribute to the literature currently available about factors associated with use of breast cancer screening among low-income women.

The Suffolk (NY) County Department of Health Services provides funding for five health centers that are located in the project's study towns (three centers are in the town of Brookhaven, two are in the town of Islip). Because there is no county hospital, these health centers play an important role in providing ambulatory

At the time of the study the authors were with the Department of Preventive Medicine in the School of Medicine, State University of New York at Stony Brook.

This paper was submitted to the journal May 28, 1991, and accepted with revisions October 1, 1991.

care services for low-income residents. At the time of the baseline survey, mammography services were not available at the health center sites, nor were they paid for by the county; thus, health center women were referred to private radiologists or hospitals for mammography.

Study Samples

A telephone survey was conducted in 1988 on a random sample of women aged 50 to 75, selected from computer files of women who had visited one or more of the five health centers for any reason within the prior year. Random samples were drawn to obtain 400 completed interviews in each of the two intervention towns in which the health centers were located. The sampling was proportionate to the total number of women visiting each health center in that town. Although possible telephone numbers for many women in the sample were obtained from health center records, the interviewers required additional searches. These entailed the use of standard telephone and cross-reference directories, and calls to information operators and to persons with the same surname as sampled patients. The response rate resulting from these procedures was 60.4%. Lack of a known telephone number was the most common reason for nonresponse, and the participation rate among persons with apparently correct telephone numbers was 74%. Because the proportion of women without a telephone number who had moved out of the area was unknown and we were interested only in women who were still residing in the study towns, 60.4% is an underestimate of the "true" response rate, which lies somewhere between 60% and 74%. The proportion of respondents from each of the five health centers ranged from 13% to 34%.

The same survey was also conducted in 1988 by random-digit dialing to obtain at least 500 interviews of women aged 50 to 75 residing in the entire project intervention area, which included three towns. The estimated response rate was 73.1%. Nonresidential numbers and numbers not in service were excluded. Eligible households were those with one or more women aged 50 to 75 living in the study area. Reasons why eligibility could not be determined include household's refusal to participate prior to screening for eligibility, use of continuous answering machine, and inability to speak one of the four interviewing languages. The proportion of eligibles among those screened was 29.6%. Among households that did not answer after nine attempts, a maximum of 10% of the phone numbers called were estimated to be current residential numbers based on prior experiments conducted by the contractor (Northeast Research in Orono, Me). The proportion of eligibles among those not screened for eligibility was unknown but was estimated to be the same as that among those screened. A methodological article about our community population survey provides a detailed discussion of the response rate calculation.[7] Data in this paper cover only the two towns in which the health centers are located.

Because only 5% of respondents to the community survey reported a health center as their regular source of care and 87% cited a private physician, there is little overlap between this group and the health center respondents. The two samples, however, may differ in the frequency of recent contact with a physician. The health center sample was restricted to women known to have visited the health center for any reason during the past year, including visits involving physician contacts. Unfortunately, in an effort to limit the length of the survey so it could be completed in 10 minutes, one question that was omitted from the 1988 telephone surveys was whether respondents had visited a physician in the past year. However, in a 1989 survey of women known to have visited a health center during the past year, 96% reported having seen a physician for any reason that year, compared with 83% in a random sample of community women surveyed by mail. This suggests that there probably was not a large difference between the samples in terms of recent contact with a physician.

In the survey, women were asked about their current breast cancer screening practices, their concerns that would influence their participation in screening or having a mammogram, their knowledge and attitudes related to breast cancer risk and the benefits of screening, their sources of health care and health insurance, their demographic characteristics, and their personal history of breast cancer. Those with a prior history of breast cancer were excluded from the analysis. Women were asked to rank their level of concern on a scale of 1 to 5, where 1 is "no concern" and 5 is "a great deal of concern."

Analysis

Chi-square tests were performed using an SAS mainframe program to compare various characteristics of the health center and community survey respondents. Tests with one degree of freedom (*df*) were continuity corrected. The *P* values in the tables are reported to three decimal places (as low as $P < .001$). Because of large sample sizes in some comparisons, the attainment of statistical significance may not indicate meaningful differences, and the magnitude of the differences in proportions should be considered.

Results

Sociodemographic Characteristics

As indicated in Table 1, there were significant differences between the health center and community respondents in all demographic characteristics. The health center respondents were older (43.7% aged 65 to 75 vs 31.2%) and less educated (43.0% had less than a 12th-grade education vs 20.1%); they also had a lower annual household income (52.8% made less than $15 000 vs 19.3%) and had a larger minority population (26.7% Black and Hispanic vs 6.7%). A significantly higher proportion of the health center respondents reported having a regular source of care (96.5%) compared with the community respondents (88.5%), which was statistically significant for these sample sizes ($\chi^2 = 28.744$, $df = 2$, $P < .001$).

Knowledge and Attitudes

Health center women knew less frequently than community respondents that the lifetime risk of breast cancer was about 1 in 10 (27.0% vs 33.2%; $\chi^2 = 4.577$, $df = 1$, $P < .05$), but their perception of a personal risk of breast cancer was similar to that of community respondents (likely risk = 25.0% vs 25.3%; $\chi^2 = 0.000$, $df = 1$, $P = .991$).

Health center respondents agreed strongly with statements about the benefits of mammography and early detection less frequently than did community respondents, and there was a statistically significant difference in those agreeing that there are other ways to treat breast cancer besides removing the breast and that women live longer if breast cancer is found early (Table 2).

The rank order of concerns that would influence their compliance with mammography guidelines were the same for the health center and community respondents (Table 3). A small difference between the two groups in the frequency of reporting the most common concern—the results of the mammography exam (health center = 83% vs community =

89%)—reached statistical significance (Table 3). Health center women had greater concern about cost (64%) significantly more often than did community respondents (49%) (Table 3); the level of concern with cost was also significantly higher among health center respondents (36.9% extremely concerned vs 17.1%; $\chi^2 = 74.316$, $df = 4$, $P < .001$). There was no significant difference, however, in the ranking or level of concerns about factors that might influence having a breast exam, with fear of results cited most often, followed by embarrassment.

More than 90% of women in both groups had ever heard of a mammogram, and the small difference between community women and health center women in this regard reached statistical significance (Table 4).

Screening Behavior

Despite their differences in socioeconomic status and in knowledge and attitudes, the health center and community samples differed little when asked if they had ever had a mammogram or breast exam or had had a mammogram in the past year (Table 4). Although there was some variation in mammography use in the past year by individual health centers (ranging from 23% to 41%), there was no health center where mammography use was substantially lower than it was in the community as a whole (29%). Significantly more health center women than community women reported having had a breast exam in the past year (Table 4).

Mammography use in the past year was significantly associated with income and education (and there was a trend toward declining use with increasing age) in the community sample, but there was little variation in screening use by income, educational level, or age within the health center sample (Table 5). Mammography use in the past year also did not vary significantly by race/ethnic group within the health center sample (white/non-Hispanic 28.7% [163/568], Black/non-Hispanic 28.6% [26/91], Hispanic 33.1% [40/121]; $\chi^2 = 0.945$, $df = 2$, $P = .623$); the numbers of minority persons in the community sample were too small (see Table 1) for a similar analysis. Within the health center group, mammography use in the past year was higher among those with health insurance coverage than among those without it: 32.9% for those with commercial insurance (with or without other coverage), 23.9% for those with Medicare and/or Medicaid only, and 22.6% for those without insurance ($\chi^2 = 7.658$, $df = 2$, $P = .002$). Among women

TABLE 6—Reasons for Never Having Had a Mammogram, among Women Who Never Had a Mammogram[a]

Reason	Community (n = 204) %	Health Center (n = 398) %	Statistical Tests
Not necessary/no problem	37.3	45.0	$\chi^2 = 2.983$, $df = 1$, $P = .084$
Doctor never recommended	23.0	26.4	$\chi^2 = 0.631$, $df = 1$, $P = .427$
Someone recommended against it	1.0	0.5	$\chi^2 = 0.023$, $df = 1$, $P = .878$
Never thought of it	10.8	8.5	$\chi^2 = 0.560$, $df = 1$, $P = .454$
Cost of mammogram	3.4	7.3	$\chi^2 = 2.912$, $df = 1$, $P = .088$
Concern about radiation	3.4	2.8	$\chi^2 = 0.041$, $df = 1$, $P = .840$
Fear of pain	2.0	1.3	$\chi^2 = 0.102$, $df = 1$, $P = .749$
Other	30.4	22.1	$\chi^2 = 4.512$, $df = 1$, $P = .034$
No reason given	12.2	9.8	$\chi^2 = 0.586$, $df = 1$, $P = .444$

Note. df = degree of freedom.
[a] Includes respondents who, when asked if they had ever had a mammogram, replied "no" or "don't know" or did not answer. More than one reason could be given by respondents.

who had a household income under $15 000, proportionally more than twice as many health center vs community respondents had a mammogram in the past year ($\chi^2 = 8.179$, $df = 1$, $P = .004$). Variations with demographic characteristics also applied to reports of ever having had a mammogram among the community group but not among the health center group. About half (or more) of the health center respondents had ever had a mammogram within each income, age, and race/ethnic subgroup, whereas among the community respondents this proportion varied significantly with income ($\chi^2 = 15.502$, $df = 3$, $P = .001$) and education ($\chi^2 = 20.240$, $df = 3$, $P < .001$).

Among women who had never had a mammogram, the ranking of reasons was similar for both groups of women (Table 6), the most common reason—that it was not necessary or they had no problem—was followed by lack of a doctor's recommendation. More health center women cited cost of the mammogram as a deterrent to mammography, but none of the differences in specific reasons achieved statistical significance.

Discussion

Despite lower levels of knowledge about mammography and the lifetime risk of breast cancer for women, less favorable attitudes regarding the value of early detection and mammography, and sociodemographic characteristics more typical of a disadvantaged population, health center registrants who visited a center in the year prior to the survey used breast cancer screening services at levels comparable to those of a random sample of women in the same community.

In a 1988 study of predominantly Hispanic users of a public health center in Massachusetts, where 59% of the women had ever had a mammogram (compared with 50% for all respondents in our study) and mammography use was similar across age, education, and employment subgroups, there was no comparison group from the general population.[8] In our study, income and educational level also did not significantly influence mammography use within the health center population although they were significant factors within the community; this suggests that services were available more equitably to all subgroups using the health centers. Race/ethnicity and age also did not significantly influence mammography use within the health center group.

The fact that 15% of community women vs 3% of health center women in the lowest household income category (under $15 000) indicated having no regular source of care did not account for the large difference in mammography use between the two samples of women within

this income subgroup. None of the 12 community women with household incomes under $15 000 and no regular source of care had a mammogram in the previous year, compared with 14% (2/14) of health center women in the same subgroup. Among those lowest-income women *with* a regular source of care, however, 31% (127/406) of health center women vs only 17% (11/66) of community women ($P = .02$) had a mammogram in the past year. Thus, having a health center as a source of care was critical.

Both health center and community women reported lower mammography use than is recommended in national guidelines, and they cited concerns that would deter them from obtaining such screening. Inadequate use of screening services for breast cancer reflects both patient and physician factors. Our findings suggest that physicians and others should inform women that the purpose of screening is to detect disease early, before there are symptoms, in order to reduce the high frequency of reports of never having had a mammogram because screening is not necessary or there were no "problems." Another common reason for never having had a mammogram was that the doctor did not recommend it. Research has indicated the importance of physician recommendation for patient compliance with mammography screening.[9–12] But although surveys of primary care physicians have shown some improvement in mammography referral rates since the mid 1980s, there is still inadequate physician compliance with national recommendations for mammography screening.[13–15] Finally, women's concerns about the results of mammography (Table 3) could possibly be alleviated by highlighting the benefits of screening, such as the high curability of breast cancer if detected early and the possibility of lesser surgery.

Use of mammography has been shown to decline with decreasing income in other populations.[4] As expected, cost of mammography was a greater concern among health center than among community respondents. Yet we have shown no difference in mammography use between predominantly low-income health center users and the general population, and significantly higher use within low-income health center users. These findings may be explained, in part, by differences in health care use factors—for example, all of the health center sample had visited the health center in the past year, which often included physician contact, and almost all of them considered the health center to be their regular source of care. Other features of the health center, however, may also have been important and may require examination—for example, physician behavior, such as higher referral rates of low-income women for mammography by health center providers than by other physicians.

Recent legislation that provides some coverage for screening mammography should help increase mammography use in both the community and the health centers. This includes a New York State law effective January 1989 requiring private insurance companies to provide some coverage for screening mammography, and provisions in the Medicare legislation effective in 1991 for Medicare recipients to receive coverage for a screening mammogram every other year.

The results of this study suggest an important role for health centers in accomplishing preventive medicine goals for early detection of breast cancer among the socioeconomically disadvantaged. They also show the potential for achieving equity in behavioral objectives despite lower educational levels and lower levels of understanding about screening, and they provide an example of the importance of community health centers in improving primary and preventive health care in the population served.[16] □

Geographic and Socioeconomic Variation in the Onset of Decline of Coronary Heart Disease Mortality in White Women

Steve Wing, PhD, Elizabeth Barnett, MSPH, Michele Casper, PhD, and H. A. Tyroler, MD

ABSTRACT

Background. Regional, metropolitan, and socioeconomic factors related to the onset of decline of coronary heart disease (CHD) mortality among White women are reported. Such studies are important for planning population-level interventions.

Methods. Mortality data for 1962 to 1978 were used, to estimate the year of onset of decline. Ecological analyses of socioeconomic data from the US census were used to emphasize structural and organizational aspects of changes in disease, rather than as a substitute for an individual-level design.

Results. Onset of decline of CHD mortality among White women was estimated to have occurred by 1962 in 53% of 507 state economic areas (SEAs), ranging from 79% in the Northeast to 39% in the South. Metropolitan areas experienced earlier onset of decline than did nonmetropolitan areas. Average income, education, and occupational levels were highest in early onset areas and declined across onset categories.

Conclusions. The results provide additional evidence for previously observed geographic and social patterns of CHD decline. Emphasis on structural economic factors determining the shape of the CHD epidemic curve does not detract from the medical importance of risk factors, but underscores the importance of community development to public health improvements. The results are consistent with the idea that the course of the CHD epidemic in the United States has been strongly influenced by socioeconomic development. (*Am J Public Health.* 1992;82:204–209)

Introduction

Early literature suggested that the decline of coronary heart disease (CHD) mortality began around the mid-1960s in all sociodemographic groups in the United States.[1–3] However, declining CHD mortality had been noted in California and New York a decade before the national decline began,[4,5] and a later study demonstrated evidence of substantial variation in the onset of decline among the 50 states for White women and men.[6] Our previous work has shown that geographic variation in the onset of CHD decline among White men in the United States was related to the metropolitan and socioeconomic characteristics of areas.[7,8] Regional, metropolitan, and socioeconomic characteristics related to the onset of decline of CHD mortality among White women aged 35 to 74 are reported here.

In this study we use populations as units of analysis; this design is typically called "aggregate" or "ecological." Ecological studies are generally considered to be inferior substitutes for more powerful individual designs, ideally a randomized experiment, in which information on both exposure and outcome is known for each person.[9] Although ecological studies are clearly inferior when the purpose of research is to isolate "independent" risk factor–disease associations, they are essential for addressing population characteristics such as epidemic cycles or economic relations. The ecological design is chosen here not as a substitute for a "superior" individual study, but as a tool for investigating population-level determinants of disease that cannot be addressed with individual-level study designs. An understanding of these determinants can help to delineate the public health impact of policies in areas such as economic development, housing, or agriculture, and their potential for reducing mass disease.

Methods

Individual records of underlying cause of death for all US residents for the years 1962 through 1978 were used. Because the definition of CHD was changed between the seventh (1962 to 1967) and eighth (1968 to 1978) revisions of the International Classification of Diseases (ICD), a group of seventh-revision codes believed to show good comparability with the eighth-revision definition[10] were chosen: 420, 422.1, 440, 441, and 443. The standard eighth-revision definition of 410–413 was used.

CHD deaths for White women aged 35 to 74 were grouped in 5-year age categories within each state economic area (SEA) in the continental United States. SEAs are single metropolitan counties or groups of nonmetropolitan counties. Annual SEA age-specific population counts were derived by linear intercensal interpolation for the 1960s and were available from the Census Bureau for the 1970s.

At the time of this study the authors were with the Department of Epidemiology, School of Public Health, University of North Carolina at Chapel Hill. Elizabeth Barnett is now with the Division of Maternal and Child Health, North Carolina Department of Environment, Health and Natural Resources, Raleigh, NC. Michele Casper is now with the Centers for Disease Control, Atlanta, Ga.

This paper was submitted to the journal November 9, 1990, and accepted with revisions July 17, 1991.

Age-adjusted rates for each SEA were computed by the direct method, using the total 1970 US population as the standard. More detailed information about data sources has been published previously.[11]

Quadratic regression was used to model the annual age-adjusted rates for each SEA.[6-8,12] In this model the adjusted rate is considered to be a function of an intercept, a slope due to year and a slope due to year squared. SEAs with declining rates over the entire period were considered to have experienced onset of decline in 1962 or earlier. Other SEAs were considered to have experienced onset of decline in the year of the maximum estimated rate from the quadratic regression.

The distribution of the timing of the onset of decline of CHD mortality was examined by geographic region and metropolitan status. The four standard US census region definitions were used: Northeast, South, North Central, and West.[7] SEAs were classified as metropolitan (n = 206) if the component counties were part of a standard metropolitan statistical area with a central city of more than 50 000 or a total population of 100 000 or more. Other SEAs were classified as nonmetropolitan (n = 301). Average levels of socioeconomic characteristics from the 1960 and 1970 US censuses were used to characterize each SEA. On the basis of previous work,[8] we considered three measures: percentage of families with annual income greater than $10 000, percentage of the labor force employed in white-collar occupations, and percentage of the population aged 25 and above that had completed high school or more. These measures reflect many aspects of individuals and their communities, and are considered here primarily as indicators of socioeconomic development and community resources. For example, high levels of white-collar employment reflect an area's economic base in service, government, and financial industries rather than in heavy manufacturing, agricultural, or extractive industries. White-collar employment, as an indicator of occupational structure, is as much a function of the kinds of jobs provided by a community as it is of the characteristics of the workers. The ecological use of these measures stresses not only the implications of white-collar employment for white-collar workers, but the effect of the occupational structure on health-relevant living conditions—including diet, recreation, housing, working conditions, and medical care—for the entire population.

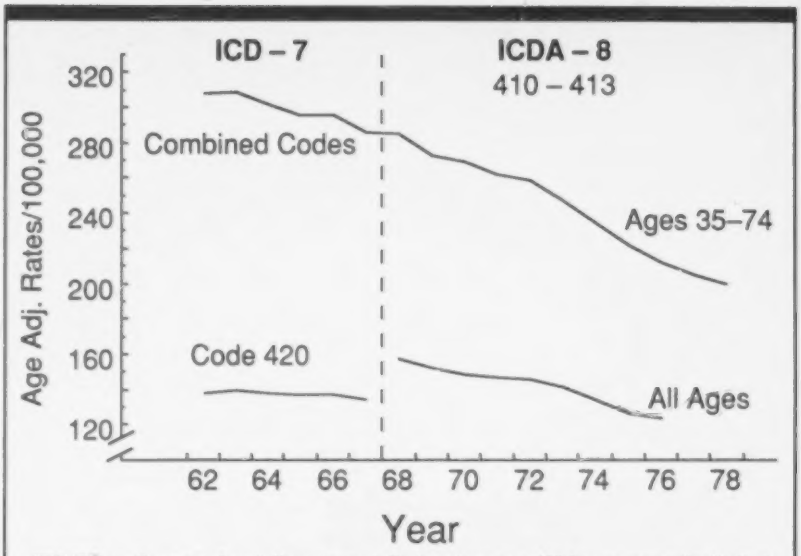

FIGURE 1—Coronary heart disease mortality trends among White women in the United States, 1962–1978: Comparison of coding schemes across ICD revisions 7 and 8.

Results

The comparability of CHD rates when two seventh-revision definitions and the standard eighth-revision definition were used is shown in Figure 1. The bottom line shows published direct-adjusted rates for all ages for ICD-7 code 420.[10] The discontinuity evident in that trend is eliminated by the recoding of seventh-revision data (codes 420, 422.1, 440, 441, and 443) shown in the top line for ages 35 to 74. Similar graphs of the recoded data for individual SEAs showed no evidence of discontinuities due to geographic variation in the comparability of the CHD definitions.

Quadratic regression estimates of the CHD mortality trend within each SEA for the years 1962 to 1978 showed that in 271 (53%) of the 507 SEAs, in which 70% of White women aged 35 to 74 resided, the highest estimated CHD rate occurred in 1962. These SEAs were classified as experiencing onset of decline in 1962 or earlier. Figure 2 shows the cumulative percentage distributions of onset of decline by metropolitan status. CHD rates in 59% of metropolitan SEAs, compared with 50% of nonmetropolitan SEAs, were estimated to have begun to decline by 1962. The earlier timing of the onset of decline in metropolitan areas was maintained through most of the distribution.

Figure 3 shows cumulative percentage distributions of onset of decline by region. The Northeast region contained the largest proportion of SEAs in onset of decline by 1962, and it remained ahead of other regions throughout the period of onset of decline. The North Central and West regions showed almost identical distributions of onset of decline; the South was later than other regions in the onset of decline. Metropolitan differentials seen for the United States were observed within each region. The more urban composition of the Northeast and the more rural composition of the South, however, did not account for the differences between these regions and the US average: 82% of metropolitan and 74% of nonmetropolitan SEAs in the Northeast were in decline by 1962, compared with 42% and 38%, respectively, in the South. Onset of decline was estimated to have occurred after 1968 in 40 SEAs, of which 35 were in the South. The Appendix gives percentages of SEAs experiencing onset of decline of CHD mortality in different time periods by metropolitan status and region.

Figure 4 shows average levels of 1970 socioeconomic indicators among SEAs grouped into four categories of onset of decline: 1962 or earlier, 1963 to 1965, 1966 to 1968, and 1969 or later. SEAs in the earliest onset-of-decline category show the highest levels of each of the three measures (percentage of families with annual income greater than $10 000, proportion of the labor force in white-collar jobs, and proportion of the population aged 25 and above with a high school diploma). SEAs in later onset-of-decline categories show progressively lower proportions of the population

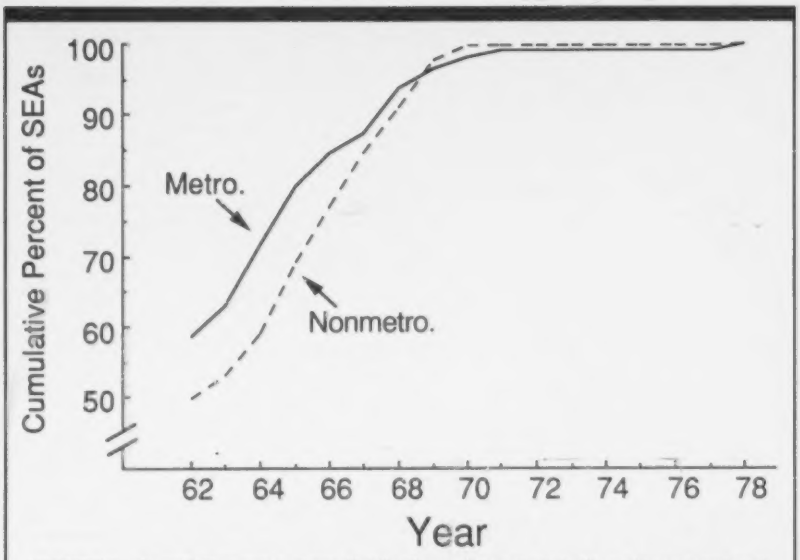

FIGURE 2—Cumulative percentage distributions of onset of decline of coronary heart disease mortality among White women aged 35–74, by metropolitan status.

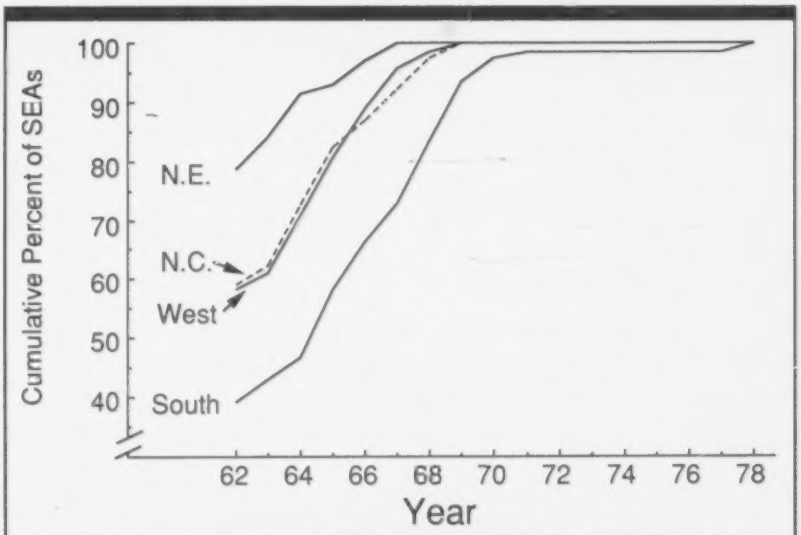

FIGURE 3—Cumulative percentage distributions of onset of decline of coronary heart disease mortality among White women aged 35–74, by region.

with high levels of these indicators. An examination of the average socioeconomic characteristics of SEAs by onset of decline separately within region and metropolitan status categories (data not presented) showed differences in the same direction but of smaller magnitude. Analyses using 1960 census indicators of socioeconomic conditions showed similar results.

The estimated time period of onset of decline of each of the 507 SEAs of the continental United States is shown on the map (Figure 5). Variability in onset of decline is evident in all regions and in most states. Spatial concentrations of early onset of decline are evident in the Northeast and West, whereas concentrations of late-onset areas appear in the South, especially in the area from Oklahoma through the Mississippi Delta to Georgia and in eastern Tennessee and Kentucky.

Discussion

In general, areas in the United States experiencing earlier onset of decline of CHD mortality among White women showed higher levels of socioeconomic indicators than areas experiencing later onset of decline. These early-onset areas tended to be metropolitan areas and areas outside the South. This pattern of onset of decline is similar to the pattern reported earlier for White men in the United States[7,8] and also to the pattern reported for White men in the Netherlands, where data for women were not analyzed.[12] The current results provide additional quantitative evidence for the previously observed geographic patterns.

Results of such ecological studies are often interpreted as reflecting differentials occurring among individuals; for example, it may be argued that places have earlier onset of decline because there are greater proportions of individuals of higher socioeconomic status there. Some evidence supports this interpretation for CHD mortality among men[13,14] and for changes in smoking behavior,[15] an important risk factor for CHD. However, ecological studies remain a poor method of isolating individual risk factor–disease associations, owing to the many potential ambiguities of that interpretation.[9]

The information used to evaluate the plausibility of findings about risk factor–disease relationships is usually derived primarily from genetic, behavioral, physiological, and clinical disciplines. These epidemiological perspectives emphasize aspects of individuals rather than the organization of individuals in groups, and they focus on the roles of agents (physical, biological, or psychosocial) in the production of disease in individuals. The potential strength of the ecological approach, on the other hand, is in understanding the production of disease in populations viewed not merely as numbers of individuals, but as organized groups with structures and relationships that create health and disease. In order to realize this strength, epidemiological information on risk factors must be combined with perspectives on populations as organized systems. These perspectives are better developed in areas such as ecology, evolutionary biology, history, sociology, and political economy than in molecular and clinical disciplines. An ecological approach to epidemiology can use these perspectives to provide an alternative account of the causes of disease in populations.

Ecological studies are crucial to a public health epidemiology (as it may now be distinguished from a clinical epidemiology) because they suggest mechanisms

of disease production and possibilities for intervention that involve human populations as organized systems.[16,17] In the case of the study of geographic variation in the onset of decline of CHD mortality, we recognize that areas experience historical economic and social development with profound implications for industrial structure, local wages, educational resources, food supplies, recreational opportunities, and ability to attract medical personnel and facilities. Studies of the mechanisms through which these processes may affect population distributions of risk factors and disease trends are part of developing the ecological view.

In the United States, the Northeast has traditionally been a rich economic area in relation to the poorer South, which has provided raw materials and cheap labor to capital centers of the Northeast.[18,19] Despite some evidence of regional convergence of incomes during the 1960 to 1976 time period, especially for advantaged workers, a substantial South–non-South gap was still present for blue-collar and less educated workers.[20] Additionally, a metropolitan–nonmetropolitan gap in industrial base, occupational structure, wages, and living conditions has developed within the South.[21] Interestingly, the metropolitan differential in the onset of decline of CHD in White women in the South appears to be smaller than the metropolitan differential in other regions (Appendix); however, the growing inequality of CHD mortality in White men and women between areas classified on the basis of occupational structure is clearer in the South than in other regions of the country.[22] As we have noted previously,[7] factors may affect the onset of decline and the rate of decline in different ways.

The delayed onset of decline of CHD mortality in the South compared with the rest of the United States (Figure 3) is consistent with the South's historical underdevelopment. This "regional colonialism"[18] has been implicated in epidemic patterns of hookworm and pellagra in the early 20th century,[23,24] and suggests continuity of structural determinants of health during the transition from "old" to "new" diseases as the major public health problems. Such historical continuity of disease causation in populations implies an alternative understanding of epidemiological transition, which has traditionally been seen as involving a parallel change in the *causes* of health problems and the major diseases of a particular period.[25] With respect to understanding and reducing poor

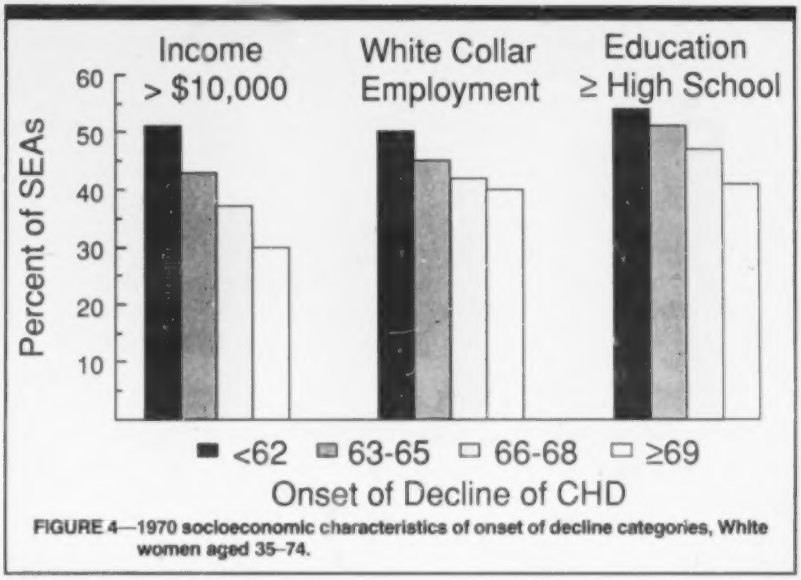

FIGURE 4—1970 socioeconomic characteristics of onset of decline categories, White women aged 35–74.

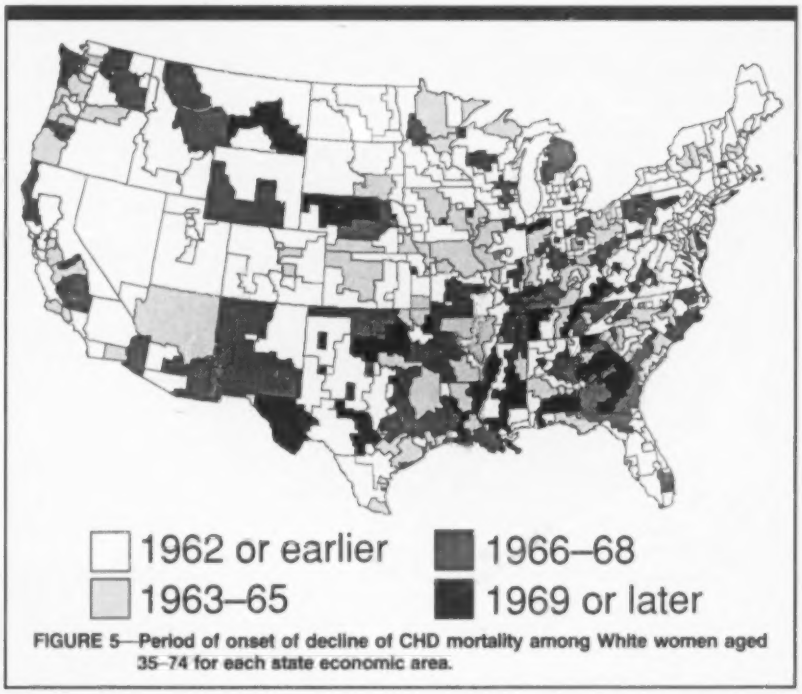

FIGURE 5—Period of onset of decline of CHD mortality among White women aged 35–74 for each state economic area.

health conditions in the South, the major diseases and disease agents may change while the population-level relations that determine their distribution are maintained. An analogous situation could be described in the experience of epidemiologic transition in some underdeveloped countries.[26]

When population relationships of development and underdevelopment are stable through epidemiological transition, the association between population characteristics and disease can change dramatically. For example, areas that experienced earlier onset of decline of CHD mortality in the period covered in this study showed a more rapid increase of cardiovascular mortality during the 1930s.[27] The epidemic of CHD accompanied rising levels of affluence that brought more atherogenic diets, physical inactivity, and increased cigarette smoking. Ironically, this relative affluence resulted from hard manual labor and lower consumption

by underdeveloped populations in the United States and abroad, factors that simultaneously limited the CHD epidemic in these populations but maintained high levels of other diseases. Now, while risk factor reduction is taking place in some more affluent populations, smaller reductions or increases are simultaneously occurring in less developed areas.

The public health potential of these ecological interpretations rests on the assumption that community resources and public policies condition options and choices of behavior in diet, smoking, physical activity, and medical care utilization (especially in a country without a national medical care system).[28] A number of theorists have suggested specific forms of economic development that should be conducive to health, such as emphasis on local ownership to prevent the outflow of profits and to reduce incentives for industries to relocate to take advantage of cheaper labor or materials.[29] Although economic conditions related to basic living conditions may have the greatest potential for improving public health, such broad issues have political dimensions that limit their potential as direct public health interventions. Those changes will occur only as a function of a more broadly conceived social agenda.

Other ecological aspects of risk factor and disease distributions, however, may offer more realistic possibilities as public health interventions, because they involve medically recognized disease agents. For example, cigarette smoking and dietary fat are relevant to the epidemic pattern of CHD. It has been well documented that declines in smoking among higher-status individuals have been followed by more aggressive marketing of tobacco to the poor, racial minorities, and women, both in the United States and abroad.[30,31] The geographic dimension of this marketing process may contribute to the patterns of onset of decline of CHD noted here as well as to growing geographic inequalities in CHD mortality. Empirical analyses documenting geographic variation in trends in tobacco advertising and consumption, if consistent with this interpretation, would support public health policies aimed at controlling tobacco production and marketing, because such interventions would protect against the shifting of consumption from populations in more developed to those in less developed areas.[32] A similar situation could be described for production and marketing of high-fat foods, which are being forsaken, to some degree, by the better educated and are being marketed in less developed areas. This situation extends even to the distribution of free dairy products, such as cheese, in government programs. These ecological mechanisms suggest that interventions in agricultural policy and marketing could be effective environmental controls on the population distribution of heart disease.[33] Because they involve more focused mechanisms than economic interventions targeted directly at community development, they constitute more realistic short-term health policy objectives.

The results presented here suggest that the onset of decline of CHD mortality in White women has been related to historical patterns of economic development in the United States. These analyses represent the first evidence, to our knowledge, of such patterns among women, inasmuch as previous analyses for the United States and the Netherlands excluded women.[7,8,11] Internationally, CHD mortality levels and trends have shown less variability for women than for men,[34] but the onset of decline of CHD mortality in the United States appears to show at least as much variability in women as in men, and a clear pattern of differences between the South and other regions. We use the ecological study design to stress structural mechanisms operating in populations rather than to isolate risk factor–disease associations that could be better studied through an individual-level design. This epidemiological approach focuses on the determinants of the population distribution of disease rather than on the identification of specific risk factors, and draws attention to mechanisms involving the organization and relations of populations in addition to the behaviors, exposures, and pathologies of individuals; the logic is economic and environmental as well as clinical and behavioral. Future empirical work documenting the ecological determinants of the distributions of known risk factors could contribute to the development of preventive measures to create healthier environments. □

Nonmetro	45	55.6	17.8	24.4	2.2

Note. Thirty-five of the 40 SEAs in category 4 are in the South.

Vaginal Douching among Women of Reproductive Age in the United States: 1988

ABSTRACT

Background. Vaginal douching has been associated with pelvic inflammatory disease (PID) in several epidemiologic studies.

Methods. To determine the extent to which douching is practiced and to describe the population subgroups in which it is most prevalent, we analyzed data from the 1988 National Survey of Family Growth, which is based on a nationally representative sample of 8450 United States women between the ages of 15 and 44 years.

Results. Thirty-seven percent of the sample reported douching; 18% douched at least once a week. The variable most strongly and consistently associated with douching was race: two thirds of Black women, but only one third of White women, reported douching. The practice was least frequent among 15- to 19-year-olds (31%) and most frequent among 20- to 24-year-olds (41%). Douching was more common among women who lived in poverty (50%) than among those who did not (28%). Seventy percent of Black women living in poverty reported douching. Women with less than a high school education were almost four times more likely to report douching as those with 16 or more years of schooling (56% vs 16%). Women with only 1 partner and those with 10 or more partners were less likely to douche than others. Sixteen percent of women who reported douching, compared with 10% of those who did not, also reported a history of PID.

Conclusions. Douching may be a modifiable risk factor for PID, it should be a high priority for future etiologic research. (*Am J Public Health.* 1992;82:210–214)

Sevgi Okten Aral, PhD, William D. Mosher, PhD, and Willard Cates, Jr, MD, MPH

Introduction

Vaginal douching is an ancient practice traditionally used for cleansing the vagina. It is apparently common today. In 1984, 32% of women over the age of 18 reported having douched within the previous week.[1] Almost 70% of sexually active adolescent women who learned about douching from their mothers practiced it.[2] However, douching may be dangerous. The practice has been associated with pelvic inflammatory disease (PID)[1,3–5] and ectopic pregnancy.[6,7] Douching remained a statistically significant risk factor for these conditions, even after the effects of demographic factors, microbiologic factors, sexual history, and other behavioral factors were controlled. Mechanisms by which douching might facilitate PID include altering the vaginal environment toward more pathogenic organisms and flushing vaginal and cervical pathogens into the uterus and fallopian tubes.[8]

If douching is in fact a risk factor for PID, a health education campaign against the practice may help to reduce PID and its sequelae. The impact of such preventive interventions depends on the prevalence of douching in the population; the greatest effect will be observed in those subgroups in which the practice of douching is most widespread. The prevalence of douching varies both geographically and demographically throughout the United States.[9,10] In selected studies, the practice has been reported more frequently by Black women than by others.[1–3]

In this article, we report our findings on the prevalence of vaginal douching among a nationally representative sample of American women of reproductive age. We discuss the distribution of douching practices by demographic (age, race, marital status, education, and poverty level), ecologic (geographic region and urban residence), behavioral (age at first intercourse, number of lifetime sexual partners), and medical (past history of sexually transmitted disease [STD] and PID) characteristics. We also present data on the frequency of douching and its timing in relation to sexual intercourse.

Methods

This analysis is based on data collected by the National Survey of Family Growth (NSFG), Cycle IV, conducted in 1988 by the National Center for Health Statistics. The NSFG, a periodic survey of women of reproductive age, provides information on contraception, infertility, reproductive health, and prenatal care. The Cycle IV survey was conducted with a multistage probability sample of 8450 women of reproductive age. The sample included 5354 White women, 2771 Black women, and 325 women of other races. The data were collected through structured personal interviews. Response rates were high overall (82.5%), and were similar for Black (82.2%) and White (82.6%) women.

The percentages reported in this article are weighted national estimates. The

weight for each respondent represents her probability of selection for the survey, adjusted for nonresponse from women with similar characteristics and adjusted to agree with United States Bureau of the Census estimates by age, race, marital status, and parity. For the first time since 1976, the 1988 NSFG included questions on vaginal douching. Respondents who had ever had intercourse were asked if they douched regularly; if they douched after sexual intercourse, at other times, or both; and how often they douched. We excluded from our analysis 16 women for whom we had no data on douching. Thus, our analysis is based on 7603 women who had ever had intercourse—4786 White, 2554 Black, and 263 of other races. The data represent national estimates of the percentage of sexually experienced women who douche regularly.

We used normal deviate tests (Z tests) to test the statistical significance of differences between proportions. We estimated sampling errors using the balanced half-sample replication technique.[11] This technique takes into account the sample design on which the weighted percentages are based. It does *not* assume simple random sampling. To determine which variables were independently associated with douching when the effects of other variables were controlled, we used multiple logistic regression.

We conducted the multiple logistic regression analysis first for all women, using race as a predictor variable. Since race was such a powerful predictor, we repeated the logistic regression analysis separately for Black and White women. We ran each logistic regression equation two ways: first with unweighted data, and second with the weights to correct for the differential sampling rates and approximate number of sample cases. The results were similar using both approaches. We present the results of the weighted analysis.

Results

Overall, in 1988, over one third (37%) of women of reproductive age reported douching (see Table 1). Race was strongly and consistently associated with douching practices. Two thirds of Black women, but only one third of White women, reported douching. The prevalence of douching by women of either race was lowest for teenagers. However, after age 19, the proportion douching increased by 10 percentage points for both Black and White women and remained quite stable thereafter. More formerly married women than currently married women reported douching; the never-married fell in the middle.

Education was inversely related to douching, and the effect of education was greater among White than among Black women. White women with less than a high school education were almost four times more likely to douche than White college graduates, whereas Black women with less than a high school education were only 40% more likely to douche than Black college graduates. Poverty was also inversely related to douching. As with education, the effect of poverty was greater among Whites than among Blacks. White women living in poverty were 54% more likely to douche than those in the highest income group, while Black women living in poverty were only 16% more likely to do so.

Slightly more of the women residing in nonmetropolitan areas douched than did those living in metropolitan areas. White women living in nonmetropolitan areas were more likely to douche than were White women living in metropolitan areas. Differences among Blacks were not statistically significant. The lowest percentage of women reporting douching lived in the western United States, and the highest percentage lived in the South. About 42% of White women living in the South reported douching regularly, compared with 26% to 28% of those who live in other regions ($P < .001$). Differences were smaller among Blacks. The interregional variability in vaginal douching practices was greater for Whites (range = 16 percentage points) than for Blacks (range = 10 percentage points).

Vaginal douching was more common among women who engaged in sexual intercourse earlier in life (see Table 2). Compared with members of the same race who had their first sexual experience after age 19, White women who began having sexual intercourse before age 15 were 1.6 times more likely, and Black women who began having sexual intercourse before age 15 were 1.2 times more likely, to douche regularly.

The relationship between douching and number of lifetime sex partners was bell-shaped. Women who had had only 1 partner were the least likely to douche, and women with 2 to 9 partners were the most likely to douche; those who reported 10 or more partners fell in the middle. This pattern was consistent for both Blacks and Whites.

Past history of STD and past history of PID were associated with douching patterns in opposite ways. Women who had a history of STD (gonorrhea, chlamydia, herpes infection, or genital warts) were less likely to douche than those who did not report a history of STD. Conversely, women who reported a history of PID were more likely to douche regularly than were women who did not have a history of PID. The patterns of association between douching and past history of PID and STD were consistent for both races.

Among women who reported douching regularly, most (71%) douched infrequently—once a week or less often (see Table 3). Black women who douched tended to douche more frequently than White women. More than one third of Blacks, but only one fourth of Whites who douched did so two or more times per week. Most women who douched reported douching both after intercourse and at other times. Only 5% reported douching only after intercourse. Of the women who douched following sexual intercourse, 36% did so within 30 minutes.

In the multiple logistic regression analysis for all women, race emerged as the single most important predictor. When the effects of age, education, income, age at first sexual intercourse, and number of lifetime partners were controlled, the analysis showed that almost four times as many Black women as White women douched regularly. Education, age, and age at first intercourse also had statistically significant effects on douching. Income and number of lifetime sex partners did not have any significant effect on douching when the other demographic and behavioral variables were controlled.

After 30 minutes	63.6	67.7	57.4

Note. All White–Black differences in this table are statistically significant at $P < .001$, except for the difference for frequency of douching ≤ 1 time per month, which is statistically significant at $P < .05$.
[a]These figures represent percentages of women who douche regularly.
[b]These figures represent percentages of women who douche after intercourse.

Multivariate analysis showed that for all races, factors significantly associated with douching were age, race, education, and age at first intercourse. The results for White women were similar to those for all races. When all other variables were controlled, education had the greatest effect on likelihood of douching. Age and age at first intercourse also emerged as independent predictors of douching with statistically significant effects. Number of lifetime sex partners and income had no independent effect when the other variables were controlled. For Black women, only education and age at first intercourse had independent, statistically significant effects when the other variables were controlled. The demographic and behavioral characteristics we examined did not pre-

dict douching as well for Blacks as they did for Whites, as suggested by the smaller chi-square value for Blacks (34.6) than for Whites (327.8).

Discussion

We found a relatively high prevalence of vaginal douching (37%) among women of reproductive age. These are the first nationally representative, systematically collected data on levels of douching. Only one other investigation, a prevalence study sponsored by a manufacturer, had surveyed douching levels in a nationwide sample of women. According to that marketing survey, conducted in 1984, 32% of women had douched during the previous week,[1] a prevalence remarkably consistent with our finding of 37%. Other surveys of convenience samples had found douching prevalences ranging from 43% to 57%.[9,10]

Race was the most important predictor of douching. Prevalence was particularly high among Blacks. Education and age at first intercourse, the two independent predictors of douching among both White and Black women, were more strongly correlated with douching among White than among Black women. We believe the high prevalence of the practice among Blacks did not allow much variability across categories of any of the predictor variables, and made it difficult for any demographic, ecologic, or behavioral variable to emerge as a powerful predictor.

In a recent report, douching emerged as an important risk factor for PID among White women but not among Black women, due to the high prevalence of the practice among Black controls.[3] Further analyses of the NSFG data indicate that douching is independently associated with PID, even when number of sex partners, age, STD history, age at first intercourse, and marital status (among White women, but not among Black women) are controlled.[12] Overall, 16% of women who reported douching, compared with 10% of those who did not, also reported a history of PID.[12]

Sparse data exist on cultural determinants of the markedly higher douching level in Blacks. Possible explanations include (1) cultural tradition handed down between generations,[2,13] (2) a greater belief in douching as an effective contraceptive practice, and (3) relatively greater marketing of commercial douches in Black communities. Nor do our findings on douching practices help us choose among alternative cultural explanations for higher douching levels among Blacks. We found that Black women douche more frequently; more of them douche after sexual intercourse, and they douche sooner after intercourse, than do Whites.

Our multivariate analysis revealed that neither income nor number of lifetime sex partners were predictors of vaginal douching. We believe this is an artifact of multicollinearity in the data. Income and education are so highly correlated that when the effect of one is statistically eliminated, it is difficult to show the effect of the other.[14] Education was entered into the regression model at the same time as income, and had a masking influence on the latter. Similarly, age at first intercourse and number of lifetime sex partners are highly correlated.

Our findings agree in many ways with the results of earlier studies. For example, a high prevalence of vaginal douching,[1] especially among Blacks,[1,9] has been reported by others. Conversely, some of our findings disagree with earlier reports. In our study, women residing in the western United States had the lowest prevalence of douching; in an earlier report, women from that region had the highest douching prevalence.[1,10] However, previously reported patterns of douching practices were based on surveys of nonrepresentative samples, and are therefore subject to possible measurement errors. Since our data are based on a nationally representative random sample of women of reproductive age, it is unlikely that our findings are affected by sampling bias.

Our finding that vaginal douching is positively associated with a history of PID but negatively associated with a history of gonorrhea, chlamydia trachomatis, genital herpes, or genital warts is consistent with earlier findings.[1,3] If true, this finding suggests that the association between PID and douching is not an artifact of STD, whereby women with STD douche to clear vaginal symptoms, as has been suggested.[15] Rather, despite the lower prevalence of vaginal douching among those who have ever had an STD, women with a history of PID are more likely to douche.

The correlation between douching and PID is also consistent with studies that show strong independent associations between PID sequelae and douching practices.[6,7] Ectopic pregnancy remained correlated with douching even after history of STD and PID[6] and serologic evidence of previous chlamydial infection[3] were controlled. Evidence on the relationship between PID-related tubal infertility and douching is sparse. Douching after menses appears unrelated to risk for primary infertility associated with endometriosis.[16] However, douching has been correlated with an increased risk for cervical carcinoma.[17]

Despite many consistencies among different investigations, the role of douching in the etiology of PID remains difficult to unravel. Plausible associations exist between douching and exposure to sexually transmitted pathogens, acquisition of infection when exposed, development of symptoms, persistence of symptoms and related health care seeking, diagnosis, and development of PID. Moreover, many of these associations are in opposite directions. For example, earlier studies suggested that douching might be useful in preventing and treating vaginal infections.[18–20] Thus, the association between douching and PID may result from (or may be masked by) confounding by sexual, health care seeking, or health provider behaviors.

Because douching is such a common practice in American women of reproductive age and because it may represent a modifiable risk factor for PID and its sequelae, we feel it should be a high priority for future etiologic research. Historical cohort studies, if possible, would provide the most rapidly obtained confirmatory data. These studies might also explore whether any particular aspect of douching practice, such as timing, frequency, or solution used, is most harmful. In addition, reasons for the racial disparity in douching practices need to be investigated. If douching emerges as a true risk factor for PID, this knowledge will be essential in guiding the content of health education campaigns. □

15th Annual National Conference on Rural Health to Be Held in DC

The National Rural Health Association will hold its 15th annual national conference on rural health, "Rural Health: Caring for the Country," May 6 to 9, 1992, at the Hyatt Regency Crystal City Hotel in Washington, DC.

The conference is designed to

- Develop practical skills and techniques in health services administration, organization, and research
- Present practical clinical sessions of interest to rural health providers
- Showcase current policy issues affecting rural health services
- Report the results of research applicable to rural health service administrators and providers

The conference program includes exhibits as well as award presentations recognizing outstanding achievement of rural health care providers, practices, programs, and research. To receive registration information, contact Robert Quick, 301 East Armour Boulevard, Suite 420, Kansas City, MO 64111. (Tel: 816/756-3140.)

Co-sponsors of the conference include the Center on Rural Elderly at the University of Missouri–Kansas City, the National Clearinghouse for Primary Care Information, the National Rural and Small Schools Consortium, and the National Rural Health Network (a subsidiary of the National Rural Electric Cooperative Association). Conference cohosts are the American Society of Hospital Pharmacists, the American College of Preventive Medicine, and the National Association of County Health Officials.

Employment Status and Heart Disease Risk Factors in Middle-Aged Women: The Rancho Bernardo Study

Donna Kritz-Silverstein, PhD, Deborah L. Wingard, PhD, and Elizabeth Barrett-Connor, MD

ABSTRACT

Background. In recent years, an increasing number of women have been entering the labor force. It is known that in men, employment is related to heart disease risk, but there are few studies examining this association among women.

Methods. The relation between employment status and heart disease risk factors including lipid and lipoprotein levels, systolic and diastolic blood pressure, fasting and postchallenge plasma glucose and insulin levels, was examined in 242 women aged 40 to 59 years, who were participants in the Rancho Bernardo Heart and Chronic Disease Survey. At the time of a follow-up clinic visit between 1984 and 1987, 46.7% were employed, primarily in managerial positions.

Results. Employed women smoked fewer cigarettes, drank less alcohol, and exercised more than unemployed women, but these differences were not statistically significant. After adjustment for covariates, employed women had significantly lower total cholesterol and fasting plasma glucose levels than unemployed women. Differences on other biological variables, although not statistically significant, also favored the employed women.

Conclusions. Results of this study suggest that middle-aged women employed in managerial positions are healthier than unemployed women. (*Am J Public Health.* 1992;82:215–219)

Introduction

Heart disease is the leading cause of death among both men and women.[1,2] In men, risk of heart disease is related to employment.[3,4] However, although more and more women have been entering the labor force in recent years,[5–7] few studies have examined employment and heart disease risk factors in women, and their findings have been inconsistent.[3,4,8–10].

Among young women in the Framingham Offspring Study, homemakers and those employed outside the home were compared and showed no significant differences in blood pressure, total cholesterol, high-density lipoprotein (HDL) level, or low-density lipoprotein (LDL) level over an 8-year period.[10] In contrast, Hazuda et al.[9] found highly significant differences in HDL and in ratio of HDL to total cholesterol, triglycerides, and fasting and postchallenge plasma glucose favoring employed women over homemakers. These differences were not explained by age, socioeconomic status, obesity, exercise, smoking, alcohol consumption, or use of estrogen.

We studied the association of employment status and heart disease risk factors in middle-aged White women. We examined differences between employed and nonemployed women in blood pressure, lipid and lipoprotein levels, and fasting and postchallenge plasma glucose and insulin levels before and after adjusting for potentially confounding physical and lifestyle covariates.

Methods

The population consisted of women who were initially enrolled in the Rancho Bernardo Heart and Chronic Disease Survey between 1972 and 1974 and who attended a follow-up clinic visit between 1984 and 1987; 84% of surviving women aged 40 and older responded. This report is based on the 242 women aged 40 through 59 at the follow-up visit who had fasted the requested 12 hours and were not currently taking lipid-lowering medications. This age group was chosen for analysis because there were too few women over age 59 who were still working. Only one woman was excluded for not fasting the requested 12 hours, and three women were excluded because they were using lipid-lowering medications.

Data Collection

A standardized interview was used to obtain information on current employment status, marital status, cigarette smoking, alcohol consumption (number of drinks per week of beer, wine, or liquor converted to milliliters of alcohol per week), and exercise (whether subjects exercised three or more times per week). Reported current use of estrogen and other medications was confirmed by prescriptions or pill containers brought to the clinic for that purpose.

In the clinic, height (meters), weight (kilograms), and waist and hip circumferences (centimeters) were measured with

[a]Hollingshead Index to assess social class of household was based on the usual occupation of the head of household.
*$P < .05$, **$P < .01$.

the participants in light clothing and without shoes. Body mass index (weight/height^2) and waist-hip ratio (waist circumference/hip circumference × 100) were used to estimate obesity and central adiposity, respectively.

An oral glucose tolerance test with a 75-g glucose load was performed between 7 AM and 11 AM after a 12-hour fast. Blood was obtained by venipuncture before and 2 hours after the glucose challenge.

Lipids and lipoproteins were measured in a Lipid Research Clinics laboratory under the continuous standardization program of the Centers for Disease Control in Atlanta, Ga. Fasting plasma total cholesterol and triglyceride levels were measured by enzymatic techniques with an ABA–200 biochromatic analyzer (Abbott Laboratories, Irving, Tex), a high-performance cholesterol reagent (No. 236691, Boehringer-Mannheim Diagnostics, Indianapolis, Ind), and a triglyceride agent (No. 6097, Abbot Laboratories). HDL cholesterol was measured by precipitating the other lipoproteins with heparin and manganase chloride according to the standardized procedures of the Lipid Research Clinics manual.[11] LDL cholesterol was calculated using the Friedwald formula.[12]

Plasma glucose was measured with a glucose oxidase method, and plasma insulin was measured in microunits per milliliter by radioimmunoassay in a diabetes research laboratory.[13] Insulin levels were available for subjects seen after November 4, 1985 (n = 216 for fasting plasma insulin, n = 205 for postchallenge plasma insulin).

Two blood pressure readings taken at least 30 seconds apart were obtained with a standard mercury sphygmomanometer after the participants had been seated for 5 minutes. Categorical hypertension was defined as the average of two systolic blood pressure readings equal to or greater than 160 mm Hg; or the average of two diastolic blood pressure readings equal to or greater than 95 mm Hg; or the current use of antihypertensive medication.

Data Analysis

The distributions of covariates (age, obesity, alcohol consumption, estrogen use, exercise, smoking, marital status, education, and social class, heart disease risk factors, total cholesterol, HDL, LDL, triglycerides, systolic and diastolic blood pressures, and fasting and postchallenge plasma glucose and insulin levels) were calculated separately for women working and not working outside the home.

Comparisons were made with t tests for continuous variables and with chi-square analyses for categorical variables. Comparisons were adjusted for age by analysis of covariance for continuous variables and by the Mantel-Haenzel Extension Test for categorical variables. Multiple regression analyses were used to examine the independent relation of current work status to lipid and lipoprotein levels, blood pressure, and plasma glucose and insulin levels after adjusting for other potentially confounding physical, sociodemographic, and life-style covariates. All statistical tests were two-tailed.

Results

Among this sample of women, 129 (53.3%) were employed and 113 (46.7%) were not employed outside the home at the time of the interview. Of the former group, 89 were primarily employed as managers, administrators, or business owners, Hollingshead Index[a] II and III; 9 were classified as professionals or executives, Hollingshead Index I.[14]

On average, employed women were 1.7 years younger than unemployed women ($t = 3.11$, $P < .01$). As can be seen in Table 1, after adjustment for age, employed women had a significantly higher educational level than unemployed women ($P = .04$) and were significantly less likely to be currently married ($P < .01$). Based on the Hollingshead Index of the usual occupation of the head of the household, there was no significant difference between employed and unemployed women in social class.

Although the differences were not statistically significant, employed women had a lower mean body mass index and waist-hip ratio, consumed less alcohol, were less likely to smoke cigarettes, and were more likely to exercise than unemployed women (see Table 2).

Comparisons of employed and unemployed women on other heart disease risk factors are shown in Table 3. Almost all differences favored employed women. After adjustment for age, currently employed women had significantly lower mean total and LDL cholesterol, triglyceride, and postchallenge insulin levels and lower systolic blood pressure than unemployed women. Currently employed women also had a significantly lower rate of categorically defined or treated hypertension than unemployed women. Additionally, employed women had lower fasting plasma glucose levels than unemployed women, a difference of borderline statistical significance ($P < .07$). HDL levels did not differ by employment status.

Hierarchical multiple regression analyses were performed to examine differences in heart disease risk factors between employed and unemployed women after adjusting for the potentially confounding attributes as shown in Table 4. After adjustment, employed women had total cholesterol levels that were 11.8

[a]Hollingshead Index: I = professionals, executives; II = managers, small-business owners; III = administrators; IV–X = secretaries, sales, and clerical workers.

mg/dL lower ($P < .05$) and fasting plasma glucose levels that were 4.5 mg/dL lower ($P < .05$) than unemployed women. Currently employed women also had a lower rate of hypertension, systolic blood pressures that were 3.8 mm Hg lower, and postchallenge plasma glucose levels that were 9.5 mg/dL lower than unemployed women, differences that were of clinical but not conventional statistical significance (Ps < .10). All other risk factors also favored the employed women although differences were not statistically significant. Analyses using waist-hip ratio instead of body mass index yielded similar results (data not shown).

The possibility that these results were due to a form of self-selection bias known as the healthy worker effect, whereby only the healthiest sought, secured, and maintained jobs, was tested in several ways. Comparisons were made between currently employed and unemployed women on diseases and risk factors ascertained at their baseline enrollment visit between 1972 and 1974. At enrollment, none of these women reported having had a heart attack, heart failure, or a stroke. They would have been 30 to 49 years old at that time—an age before heart or other chronic disease commonly affects the ability to work. *All* four women who reported diabetes at baseline were employed at the follow-up (1984 to 1987) visit. Regression analyses restricted to women with "normal" risk factor levels at baseline (i.e., total cholesterol below 225 mg/dL; systolic blood pressure below 140 mm Hg; fasting plasma glucose below 140 mg/dL) indicated that currently employed women had lower risk factors at follow-up (total cholesterol levels 12.9 mg/dL lower [$F = 3.75$, $P < .05$], systolic blood pressure 4.1 mm Hg lower [$F = 2.90$, $P < .08$], and fasting plasma glucose levels 5.2 mg/dL lower [$F = 5.88$, $P < .01$]) than unemployed women. Overall, these data do not support selection bias as an explanation for the more favorable risk factor status among the currently employed women.

Discussion

In the present study, women working outside the home were generally healthier than unemployed women. They had significantly lower total cholesterol and fasting plasma glucose levels than women not currently employed. Differences on all other cardiovascular disease risk factors, although not statistically significant, also favored employed women. Furthermore,

these differences were not explained by age, obesity, estrogen use, alcohol consumption, cigarette smoking, exercise, marital status, education, or socioeconomic status.

The results of the present study are in accord with those of Hazuda et al.,[9] who found more favorable lipid levels among employed Mexican-American and non-Hispanic White women after adjusting for age, obesity, socioeconomic status, smoking, exercise, alcohol use, and use of oral contraceptives. Hazuda et al.[9] also found that fasting and postchallenge plasma glucose levels differed between employed and unemployed Mexican-American women but not between employed and unemployed non-Hispanic White women, a difference that was explained by greater obesity in the former ethnic group.[9] In contrast, the present study of upper-middle-class White women, who are on average leaner than other US women,[15] found clinically significant differences in plasma glucose levels between employed and unemployed women, independent of obesity.

The results of the present study are in accord with several studies that demonstrated better self-reported health among employed women.[16-19] However, they are in contrast to results of the Framingham Heart Study,[3,8] which found employment status to have no effect on women's self-reported health. This difference may reflect the Framingham definition of working, according to which any woman who had worked outside her home for more than half her adult life was classified as employed, regardless of her current employment status. The Rancho Bernardo study considered a woman employed only if she was currently employed, the same definition used in other studies.[4,9]

Two studies have reported that the beneficial effects of working on self-reported health are greater for unmarried women than for married women.[20,21] In the present study, where over three quarters of the women were married and there were only nine single unemployed women, adjusting for marital status did not materially alter the results.

Differences did not appear to be due to the self-selection bias called the healthy worker effect, whereby only the healthiest are employed outside the home.[22] The differences between employed and unemployed women remained even after the analyses were restricted to those who had the most optimal risk factors at enrollment. Women with diabetes, the only chronic disease reported at baseline, were all employed at the time of their follow-up visit.

Differences between employed and unemployed women were not explained by differences in socioeconomic status or educational level. Furthermore, given the homogeneous, upper-middle-class status of this cohort, it is unlikely that the differences reflect differential access to medical care.

Employment could be associated with health through other life-style and behavioral factors. Although not statistically significant, differences between employed and unemployed women in obesity, alcohol consumption, cigarette smoking, estrogen use, and regular exercise tended to favor a more healthy life-style among employed women, and adjustment for these attributes reduced the differences in heart disease risk factors between these women (Table 4).

A psychosocial factor could also moderate the relationship between employment status and health. Most of these upper-middle-class women were married and were probably working for job satisfaction rather than financial need. Several studies have found that the association between employment and health is stronger for women who have a more favorable attitude toward their jobs (See Waldron and Herold 1986[23] for review).

A positive job attitude could parallel the perception of control offered by the occupational setting.[24] Individuals who feel that what happens to them is the result of factors beyond their control are said to have an external locus of control, whereas those who believe that what happens to them is the result of their own decisions are said to have an internal locus of control.[25] Those with an internal locus of control are reported to experience less illness,[26] less coronary disease,[27] less hypertension,[28] and less depression[29] than those with an external locus of control. In terms of life-style factors, those with an internal locus of control are less likely to smoke cigarettes[30] and more likely to engage in physical exercise.[31] Middle-aged employed women have been found to have a greater sense of personal control over their environment than women who are homemakers or students,[24] possibly reflecting their income and job responsibilities.

Whatever the mechanism, the present study suggests that upper-middle-class women working outside the home have more favorable heart disease risk factors than unemployed women. Given that almost 80% of the employed women studied were working as professionals, managers, or administrators, these data do not support prior predictions that, as women attain male professional- or executive-level occupations, they will also acquire male coronary heart disease risk and mortality rates.[32] □

AIDS in Bisexual Men in the United States: Epidemiology and Transmission to Women

ABSTRACT

Background. Homosexual and bisexual men with acquired immunodeficiency syndrome (AIDS) differ, and bisexual men play an important role in the sexual transmission of human immunodeficiency virus (HIV) to women.

Methods. To describe AIDS in these groups, we examined AIDS cases reported nationally through June 1990.

Results. Among 65 389 men who reported having had sex with men since 1977, 26% were bisexual. More Black (41%) and Hispanic men (31%) than White men (21%) reported bisexual behavior. Bisexual men were twice as likely to report intravenous drug use (20%) as were homosexual men (9%), regardless of race or ethnicity. Among 3555 women with heterosexually acquired AIDS, 11% reported sexual contact with a bisexual man and no other risk factor, although in some states approximately half reported such contact. In 1989, the AIDS rate due to sex with a bisexual man was three and five times higher among Hispanic and Black women, respectively, than among White women.

Conclusions. Differences between bisexual and homosexual men with AIDS and the relative importance of AIDS in women due to sexual contact with bisexual men should be considered in the development of HIV prevention programs. (*Am J Public Health.* 1992;82:220–224)

Introduction

Most reports on human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) consider bisexual and homosexual men as a single group. However, this categorization may not always be appropriate. Bisexual men may differ from homosexual men in several behavioral and epidemiologic aspects of HIV infection[1,2] and these differences have important public health implications. Interventions designed to prevent HIV transmission among homosexual men may not reach or be appropriate among bisexual men. For example, bisexual men may be less likely to identify with gay communities or to view themselves as at risk for HIV infection.[3,4] In addition, bisexual men may transmit HIV to their female partners.

In this study, we analyzed national AIDS surveillance data to compare bisexual men (men who reported sexual contact with both men and women) and homosexual men (men who reported sexual contact with men and not with women) with AIDS and to assess the relative importance of bisexual men in the heterosexual transmission of HIV to women.

Methods

We used national surveillance data for cases of AIDS in persons over 13 years of age who were reported to the Centers for Disease Control (CDC) from June 1981 through June 1990.

The sexual behavior of men was determined by using responses to the following two questions on the AIDS case report form:

> "After 1977 and preceding the diagnosis of AIDS, did this patient have sexual relations with a male partner?"
> "After 1977 and preceding the diagnosis of AIDS, did this patient have sexual relations with a female partner?"

Men were classified as homosexual if they were reported as having had sex with men and not with women, and were classified as bisexual if they were reported as having had sex with both men and women. Men who were reported as having had sex with men but for whom information on sex with women was missing were excluded.

Data on AIDS indicator diseases were also obtained from AIDS case reports; more than one condition can be specified. The surveillance definition for AIDS was revised in September 1987 to include additional indicator diseases and to accept the presumptive diagnoses of some other indicator diseases.[5] Persons meeting only the new criteria were more likely to be Black, Hispanic, or intravenous (IV) drug users[6]; therefore, we repeated our analyses, including only patients who met the pre-1987 definition. Because results were similar, we report findings based on all reported cases meeting the current case definition. Analyses of indicator conditions added with the revised case definition (e.g., wasting syndrome) were restricted to persons reported after September 1987.

A woman was classified as having AIDS due to heterosexual transmission if

Editor's Note. See related editorial by Lifson on page 166 of this issue.

she had no history of blood transfusion or IV drug use and reported having had sexual contact with a person who had AIDS or HIV infection, or with a person who had any of the following risks since 1977: IV drug use, male-to-male sexual contact, or receipt of blood or a blood product.[7] Because we were primarily interested in HIV transmission in the United States, we excluded women born in countries where heterosexual contact is the primary means of HIV transmission (i.e., African and Caribbean countries). To assess the relative importance of bisexual men in the heterosexual transmission of HIV among women, we compared the number of cases of AIDS in women attributed to sexual contact with a bisexual man with the number of cases attributed to sexual contact with a male IV drug user. We used sex- and race-specific mid-year (July 1) population estimates from public-use computer tapes prepared from Bureau of Census data to calculate annual AIDS rates.[8] Population estimates for persons of Hispanic origin were extrapolated from US Bureau of the Census reports.[9,10]

Results

Epidemiologic Differences Between Bisexual and Homosexual Men with AIDS

Complete responses to the two sexual history questions were available for 65 389 men who reported having had sex with men since 1977; of these, 16 793 (26%) also reported having had sex with women. The proportion of bisexual men has increased slightly over time, from 23% in 1983 to 26% in 1989.

For an additional 26 092 men who reported having had sex with men, information regarding sexual contact with women was missing. The distribution of characteristics for these men was intermediate to those of men classified as homosexual or bisexual, suggesting that some were bisexual and some were homosexual.

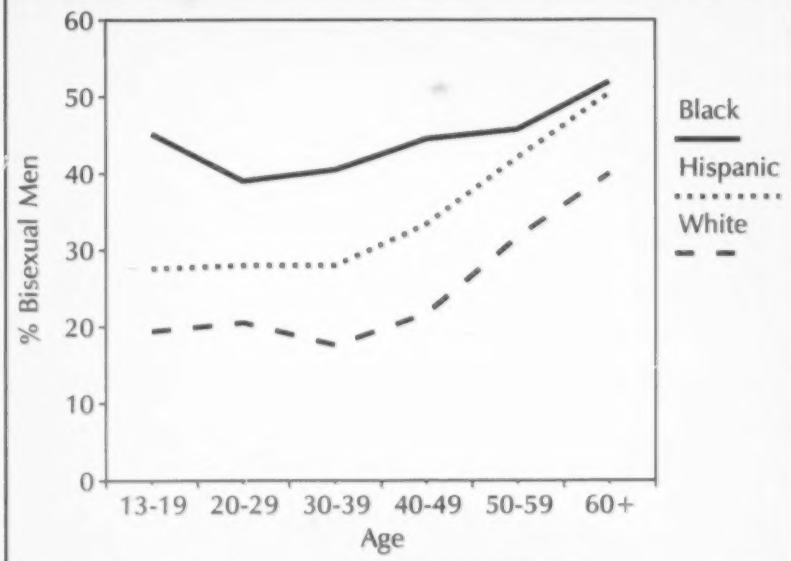
Bisexual and homosexual men differed by race/ethnicity. Among men who reported sex with men (homosexual and bisexual combined), bisexuality was reported by more Black (41%) and Hispanic (31%) men than White men (21%) (Table 1). These differences were fairly consistent over time and in different states.

The proportion of men who were bisexual increased with age after age 30 to 39 years (Figure 1). The pattern with age was consistent among racial/ethnic groups except for young Black men (13–19 years of age). These differences by age were not affected by IV drug use or year of diagnosis.

TABLE 1—Bisexual and Homosexual Men Reported with AIDS, United States, through June 1990

Race/ethnicity	Bisexual	Homosexual	% Bisexual[a]
White	9555	36 260	21
Black	4842	6851	41
Hispanic	2217	5049	31
Asian/Pacific Islander	152	367	29
American Indian/Alaskan Native	27	69	28
Total	16 793	48 596	26

Note. Men were classified as bisexual if they reported having had sex with both men and women since 1977, and were classified as homosexual if they reported having had sex with men and not with women.
[a]% Bisexual = [(number of bisexual men with AIDS)/(number of bisexual men with AIDS + number of homosexual men with AIDS)] × 100.



*Percent bisexual men = $\frac{\text{No. bisexual men with AIDS}}{\text{(No. bisexual + No. homosexual men with AIDS)}} \times 100$

FIGURE 1—Men with AIDS who had sex with men (percent bisexual), by age and race, United States, through June 1990.

Bisexual men with AIDS were twice as likely as homosexual men to report IV drug use (Table 2). The increased use of IV drugs among bisexual men was observed in each racial/ethnic group, with the most pronounced difference among Hispanic men. This difference in IV drug use between bisexual and homosexual men with AIDS was also consistent by region (IV drug use in bisexual men/IV drug use in homosexual men: Northeast, 2.4; Midwest, 2.4; South, 2.2; West, 1.9) and by year of diagnosis.

The opportunistic diseases reported for bisexual and homosexual men with AIDS were similar except for Kaposi's sarcoma and wasting syndrome. Kaposi's sarcoma (including presumptive and definitive diagnoses) was about 1.5 times more common among homosexual than among bisexual men with AIDS (Table 3). This difference persisted across different racial/ethnic groups, although the difference was smaller among Black men, and also was consistent across age groups. Although the frequency of Kaposi's sarcoma in all men with AIDS has declined over time, the difference between homosexual and bisexual men in frequency of Kaposi's sarcoma persisted by diagnosis year. For example, in 1984, 38% of homosexual men and 27% of bisexual men were reported with Kaposi's sarcoma; in 1989, 17% of

TABLE 2—History of Intravenous Drug Use in Bisexual and Homosexual Men Reported with AIDS, United States, through June 1990

	Percentage with History of Intravenous Drug Use[a]			
	White (n = 44 034)	Black (n = 10 521)	Hispanic (n = 6614)	Total[b] (n = 61 784)
Bisexual	16	23	27	20
Homosexual	8	14	11	9

[a]Excludes 1781 White, 1172 Black, and 652 Hispanic men with unknown histories of intravenous drug use.
[b]Includes 519 Asian/Pacific Islanders and 96 Native Americans.

TABLE 3—Kaposi's Sarcoma and HIV Wasting Syndrome in Bisexual and Homosexual Men Reported with AIDS, United States, through June 1990

	White	Black	Hispanic	Total
	Percentage with Kaposi's Sarcoma			
	(n = 45 815)	(n = 11 693)	(n = 7266)	(n = 65 389)
Bisexual	17	8	15	14
Homosexual	23	11	22	21
	Percentage with HIV Wasting Syndrome			
	(n = 35 077)	(n = 9764)	(n = 5754)	(n = 51 095)[b]
Bisexual	19	20	20	19
Homosexual	14	16	11	14

[a]Includes 519 Asian/Pacific Islanders and 96 Native Americans.
[b]Includes persons reported after September 1987 only; includes 410 Asian/Pacific Islanders and 90 Native Americans.

* Excludes 110 women with AIDS who reported sexual contact with both a bisexual man and an IV drug user.

FIGURE 2—Women with AIDS attributed to sexual contact with a bisexual man or sexual contact with IV drug user, United States, through June 1990.

homosexual men and 10% of bisexual men were reported with Kaposi's sarcoma. Findings were similar when IV drug users were excluded from the analyses.

Wasting syndrome was more common among bisexual men with AIDS than among homosexual men with AIDS (Table 3). This difference was consistent regardless of race or IV drug use, except for Black IV drug users, among whom no difference in the frequency of wasting syndrome was seen. This difference in wasting also was consistent by diagnosis year and by region of the United States, although the difference was greater in the US Territories (wasting diagnosis in bisexual men, 46%; in homosexual men, 36% and smaller in the West (wasting diagnosis in bisexual men, 16%; in homosexual men, 14%).

Women with AIDS Reporting Contact with a Bisexual Man

Among 3555 women with AIDS who acquired HIV infection through heterosexual contact (excluding women born in African or Caribbean countries), 11% (n = 405) reported sexual contact with a bisexual man and no other risk factor for AIDS. Another 114 women with AIDS reported sexual contact with a bisexual man and another specific heterosexual contact (an IV drug user, n = 110; a transfusion recipient or person with hemophilia, n = 4).

In 1989, the rate for AIDS due to sex with a bisexual man (and no other partner at risk) was three and five times higher among Hispanic (1.8 per 1 000 000) and Black (2.8 per 1 000 000) women, respectively, than among White women (0.6 per 1 000 000), and was seven times lower overall than the rate for AIDS due to sex with an IV drug user. However, the relative importance of AIDS attributed to sexual contact with bisexual men varied widely by state (Figure 2). In states with a relatively low HIV seroprevalence in IV drug users (e.g., California), the number of cases in women associated with sex with a bisexual man was comparable to the number associated with sex with an IV drug user. In states with high HIV seroprevalence in IV drug users (e.g., New Jersey and New York), AIDS due to sexual contact with an IV drug user accounted for most heterosexually acquired AIDS in women, regardless of race.

Discussion

Our estimate that 14% of all men with AIDS are bisexual is a minimum estimate; if the frequency of bisexuality was the same in the group with missing data as in the group with complete information, bisexual men with AIDS would represent 19% of all men with AIDS. The percentage of men who were bisexual has increased slightly over time. This increase

may be influenced by the sexual history questions, which asked only about sexual contact with men or women since 1977. Reports for more recent cases would cover a longer time period and these questions could not distinguish between early and more recent sexual behavior.

Among men with AIDS who reported having had sex with men, Blacks reported bisexuality more frequently than did Whites or Hispanics. Similar findings have been reported elsewhere. In a study of sexually transmitted disease clinic patients in Ohio, among 1107 men who reported having had sex with other men, 47% of the Black men and 27% of the White men classified themselves as bisexual.[11] In a study conducted at 20 large blood centers, 209 HIV-infected prospective male blood donors reported having had sex with men; 48% of Blacks, 36% of Hispanics, and 33% of Whites had had sex with a woman in the previous year.[3] Some have suggested that the adoption of a bisexual life-style among Black men may be related to the difficulty of being homosexual in the Black community.[1] However, these data do not enable us to distinguish between a difference in reporting and a true difference in behavior by race/ethnicity.

The Hispanic population in the United States is diverse in country of origin and degree of acculturation. Unless bisexual Hispanic men are highly acculturated, their behavior patterns may be more similar to behavioral patterns of their country of origin.[1] From studies of bisexual behavior in Mexico, it was estimated that as many as 30% of Mexican men between the ages of 15 and 25 may engage in sex with both men and women.[12] However, men who practiced the active, insertive role in male-to-male sex and who also had sex with women did not view themselves as homosexual or bisexual; thus they were a potentially difficult group to reach.[12,13] Because of the diversity of the Hispanic population, generalizations about AIDS-related behaviors must be made cautiously.[1]

Older men with AIDS who reported having had sex with men were more likely to report bisexual than homosexual behavior. This fact may represent the greater acceptance of homosexuality during the gay liberation movement of the 1960s and 1970s (a cohort effect), but we cannot exclude other reasons, such as an increasing trend with age or differences in reporting of sexual activity with age. For example, because men were asked whether they had had any male or female partners after 1977 and preceding their diagnosis of AIDS, the time period of sexual activity covered is longer for older men than for younger men, which could increase the likelihood of their having had at least one female partner.

Kaposi's sarcoma was more common in homosexual men than in bisexual men with AIDS. If bisexual men with AIDS had fewer sexual contacts with male partners than did homosexual men, this finding supports suggestions that Kaposi's sarcoma is associated with a sexually transmitted agent that is more prevalent among men who have sex with men.[14] There is some evidence that bisexual men have fewer male partners than do homosexual men. A study of 1034 single men living in San Francisco found that during a 6-month period (January to June 1984), 27% (172/641) of the homosexual men and 21% (37/173) of the bisexual men reported having had more than 10 sexual partners.[15] Preliminary data from a multicenter study of HIV-seropositive blood donors found that men who reported only homosexual contact had had a larger number of male partners since 1978 (median number of male partners = 10, n = 148) than men who reported bisexual contact (median number of male partners = 5, n = 58) (CDC, unpublished data). The hypothesis that Kaposi's sarcoma is associated with a sexually transmitted agent is also supported by the finding that Kaposi's sarcoma was more common in women who reported a bisexual male partner than in women who did not report a bisexual male partner.[14]

The higher frequency of HIV wasting syndrome in bisexual men than in homosexual men was consistently observed across racial/ethnic groups, even after the exclusion of IV drug users. This finding is more difficult to explain. Possible reasons include differences between bisexual and homosexual men with AIDS in time of diagnosis, in completeness of medical evaluation, or in conditions associated with severe weight loss.

These findings suggest that bisexual and homosexual men with AIDS are distinct. For example, more bisexual men than homosexual men reported a history of IV drug use. Similar information was found in a study of 200 male prostitutes, in which self-identified bisexual prostitutes were more likely than homosexual prostitutes to use intravenous cocaine or heroin, to be homeless, and to have "hustled" in a number of large cities.[16] Although these male prostitutes had sex for money with men, more of their other sexual encounters were with women. In preliminary data linking AIDS surveillance and death certificate information, 86% of homosexual men versus 52% of bisexual men had never married. At death, 3% of homosexual men versus 24% of bisexual men were currently married (CDC, unpublished data). Bisexual men who are married or who do not identify themselves as homosexual may be more difficult to reach, especially through gay community networks. Because of these differences, bisexual and homosexual men should be considered separately in certain research and prevention settings.

We used categories based on reported sexual behaviors, not on self-labeled sexual identity. Our "bisexual" category does not necessarily represent men who identify themselves as bisexual, but more accurately represents men with AIDS who were reported as having had sexual contact with both male and female partners since 1977. Self-identification does not necessarily predict sexual behavior, and some men who report or consider themselves to be homosexual or heterosexual actually have sex with both men and women.[1] These differences between sexual identity and sexual behavior must be considered in interpreting these findings and in counseling persons about HIV.

Nationwide, 63% of women with heterosexually acquired AIDS were infected through sexual contact with IV drug using men.[17] Rates of AIDS attributed to sexual contact with IV drug users vary widely by state and race/ethnicity, with rates ranging from 0 in some states to as high as 14.5 per 100 000 among Black women in New Jersey. Approximately 70% of all AIDS cases in women related to sexual contact with an IV drug user are reported from New York, New Jersey, Florida, and Puerto Rico. Rates of AIDS in women attributed to sexual contact with bisexual men vary less by state (ranging from 0 to 0.9 per 100 000 among black women in Florida). In some states where HIV prevalence among IV drug users is low, sexual contact with bisexual men accounts for a substantial proportion of women with heterosexually acquired AIDS.

Nearly one quarter of bisexual men with AIDS who died were married at the time of death. Because many women may not be aware of their partners' behavior,[18,19] the number of women with AIDS who have a bisexual partner is probably higher than reported. Thirteen percent of women with heterosexually acquired AIDS did not report the risk of their partner and 7% of all women with AIDS are reported without an established risk fac-

tor[7]; some of these cases may have resulted from sexual contact with bisexual men. In addition, awareness may differ by race/ethnic group; among 52 female partners of HIV-seropositive bisexual men enrolled in the California Partners' Study, 80% (28/35) of White, 20% (1/5) of Black, and 22% (2/9) of Latino women were aware of their partners' bisexuality at entry into the study.[19] Similar findings were reported from Chicago.[20] Rates for AIDS due to sexual contact with bisexual men were highest among Black and Hispanic women, yet these women may be the ones least aware of their risk. In addition, this difference in awareness would result in a greater underestimation of the rate of AIDS due to sex with bisexual men among Black and Hispanic women.

Although bisexual and homosexual men are often considered together, differences between them should be acknowledged in efforts to prevent both male-to-male and male-to-female HIV transmission. Effective AIDS risk-reduction programs that reach bisexual men who put themselves and their male and female partners at risk for HIV will require a better understanding of the patterns of bisexual behavior. Critical issues include the incidence of sexual behaviors with male and female partners, the extent of disclosure of same-sex behaviors to female partners, the social and sexual networks of bisexuals, cultural or ethnic differences in bisexual behavior, and the relationship between sexual identity and sexual behavior.[1] □

Knowledge and Attitudes about AIDS among Corporate and Public Service Employees

Judith K. Barr, ScD, Joan M. Waring, MA, and Leon J. Warshaw, MD

ABSTRACT

Background. We examined the relationship between workplace AIDS education efforts and workers' knowledge about HIV transmission and their attitudes toward coworkers with AIDS.

Methods. Questionnaires were mailed to corporate and public service workers at 12 work sites to ascertain the extent of their knowledge about AIDS and their attitudes toward coworkers with AIDS. Each work site had offered an AIDS education program. The average response rate was 40%; 3460 workers returned questionnaires.

Results. Respondents' knowledge was largely consistent with available scientific evidence. However, a substantial minority still believe HIV infection can be transmitted through casual contact. Over 30% endorse the screening of new employees for AIDS, and 23% would fear contagion from an infected coworker. Thirty percent of the respondents expressed skepticism about the veracity of information from government sources and the scientific community. Work site comparisons show that where educational programs are minimal, employees know less about HIV transmission and hold more negative attitudes.

Conclusion. Comprehensive workplace AIDS education programs can reinforce workers' knowledge about HIV transmission, thereby fostering more favorable views toward coworkers with AIDS. (*Am J Public Health.* 1992;82:225–228)

Introduction

National surveys[1] and public opinion polls[2–4] have shown that a sizeable portion of the adult population is misinformed about HIV/AIDS. Negative attitudes toward people with AIDS (PWAs) have been associated with a lack of knowledge about HIV/AIDS among the general public.[5] Studies report an association between strong workplace HIV/AIDS education efforts[6,7] and positive attitudes about HIV/AIDS in the workplace. Workplace programs increased knowledge about HIV/AIDS transmission among public high school teachers and supervisors[8] and among employees in businesses.[9] University employees' attendance at an HIV/AIDS education program was associated with positive attitudes about HIV/AIDS.[10]

This paper examines relationships between employees' knowledge about HIV transmission and their attitudes toward coworkers with HIV/AIDS. Because HIV/AIDS education in the workplace is an important source of information for workers,[11] ascertaining what employees know and think can be useful in designing programs responsive to their needs and concerns.

Methods

Employees at eight corporate work sites and four public agencies were surveyed about their knowledge and attitudes about HIV/AIDS. Each of the participating organizations had implemented an HIV/AIDS education program, ranging from simple distribution of literature to extensive efforts including printed materials, video or film presentations, and discussion sessions with medical experts; some programs were compulsory.

The sample work sites were selected because of differences in approaches to HIV/AIDS education, the diversity of work organizations and work forces, and management's interest in and willingness to cooperate with the study. The work sites were dispersed geographically (New York state, mid-Atlantic, mid-West) and included a national sales force; they represented different industries (pharmaceutical, telecommunications, banking) in the private sector and agencies in the public sector.

The questionnaires, accompanied by a cover letter from a company or agency official, were mailed in the fall of 1988. Respondents included 2836 corporate employees and 624 public service workers (n = 3460), representing an average 40% response rate (Table 1). Although the possibility of nonresponse bias cannot be ruled out, respondents and the total work force at each site did not differ appreciably in proportions of women to men (gender was the only characteristic available for comparison).

The self-administered questionnaire was adapted from the National Health Interview Survey.[12] A transmission knowledge score was formed from 12 items about the likelihood of getting HIV/AIDS through casual contact (Cronbach's alpha = .91). A workplace attitude score was formed from five items assessing at-

TABLE 1—Response Rates by Industry

	No. Sent[a]	Rate, %	No. Respondents
Private industry (total)	6728	42.2	2836
Pharmaceutical	5278	38.2	2018
Telecommunications	800	48.5	388
Banking	650	66.2	430
Public agencies (total)	2000	31.2	624
Uniformed	1500	29.0	435
Nonuniformed	500	37.8	189
Total	8728	39.6	3460

[a]Questionnaires and self-addressed postpaid envelopes were mailed by each participating organization. Respondents returned the questionnaires directly to the New York Business Group on Health. There was no identifying information on the questionnaire; a mark on the envelope identified the site.

TABLE 2—Comparison of New York Business Group on Health (NYBGH) Study Respondents (n = 3460) with Sample from National Health Interview Survey (NHIS)[12] on Selected Items: Knowledge about Transmission Through Casual Contact

	NHIS, %		NYBGH, %	
	Incorrect[a]	Correct[b]	Incorrect[a]	Correct[b]
What is the likelihood of getting AIDS or the AIDS virus from				
Living near a hospital/home for AIDS patients	12	88	4	96
Attending school with child who has AIDS virus	16	84	5	95
Eating in restaurant where cook has AIDS virus	38	62	17	83
Shaking hands/touching someone with AIDS virus	15	85	3	97
Working near someone who has AIDS virus	20	81	4	94
Sharing eating utensils with someone who has AIDS virus	41	59	20	80
Being coughed/sneezed on by someone with AIDS virus	40	60	21	79
Kissing cheek of person with AIDS virus	15	85	4	95
Kissing (with exchange of saliva) a person with AIDS virus	63	36	44	56
Using public toilets	29	71	9	91
Mosquitos or other insects	47	53	21	79
Donating or giving blood	—	—	43	58

Note. Percentages are rounded and may not add to 100.
[a]Incorrect responses included "very/somewhat likely" and "don't know."
[b]Correct responses included "very/somewhat unlikely" and "not possible."

titudes toward coworkers with AIDS (Cronbach's alpha = .85).

Nearly one fifth (18%) of the respondents (n = 627) wrote comments in the space provided on the questionnaire. Content analysis yielded 814 meaning units, which were classified into nine substantive categories.

Results

Knowledge

Employees' knowledge about HIV transmission was generally consistent with available scientific data (Table 2). Respondents from three sites (two public and one private) with minimal workplace programs (e.g., literature only, "one-shot" program, voluntary rather than compulsory) had, on average, knowledge scores significantly lower than those of respondents from the sites with more comprehensive programs (Duncan Multiple Range Test; $P < .05$).

Although these employees were more knowledgeable than a national sample[12] surveyed at about the same time (Table 2), sizable numbers still believed that HIV/AIDS can be transmitted through casual contact. Fifteen percent said transmission is possible through shared eating utensils; 17% said HIV/AIDS can be transmitted through coughing or sneezing. Thirty-nine percent thought it very or somewhat likely that HIV/AIDS can be spread through saliva in kissing.

A major theme of the volunteered written comments was concern about the risk of HIV infection through casual contact.[13] Thirty percent of the respondents expressed skepticism about the accuracy of public information, because scientific findings are sometimes reversed; lack of trust in scientific authorities; and worry that some messages are simply attempts to calm public fears. For example:

> "I feel that although we are studying the disease we still don't know everything. Ten years down the line I don't want to hear you have found AIDS *can* be transmitted by shaking hands."

> "I believe the AIDS problem is much more serious and contagious than the general public is led to believe, and that there is more known about AIDS than what is released to the public."

Attitudes

Negative and potentially discriminatory attitudes toward coworkers with HIV/AIDS were expressed by some respondents (Table 3). Nearly three fourths agreed that PWAs should be treated like other employees. However, a substantial minority said they would be uncomfortable eating lunch with PWAs, and nearly one in four would be "afraid of getting AIDS" from working near PWAs. Although few considered HIV/AIDS an acceptable reason for termination, nearly one third said employers should not hire PWAs. Workers in the uniformed public agencies had significantly less favorable attitude scores than employees in the other worksites (Duncan Multiple Range Test; $P < .05$).

The attitudes expressed in volunteered comments are consistent with these results. Many respondents (16%) were concerned about being protected from coworkers with HIV/AIDS. Comments showed that 12% favored testing, firing, or "putting them on disability" to guard uninfected employees against contact. A few (6%) expressed egalitarian views about treating PWAs fairly and compassionately.

Relationship between Knowledge and Attitudes

There was a strong positive correlation ($r = .437$, $P < .001$) between trans-

mission knowledge scores and workplace attitude scores: those who were more knowledgeable also had more favorable attitudes. Contingency analysis shows that 22% of respondents both were most knowledgeable and had the most favorable attitudes (highest two fifths on both scores), and 24% both were least knowledgeable and had the least favorable attitudes (lowest two fifths on both scores).

Yet 12% of employees with a high transmission knowledge score had only moderately favorable workplace attitudes. Although very few (2%) respondents thought it was likely that HIV/AIDS could be contracted by working near someone with AIDS, a much larger proportion (23%) said they would be afraid of infection if they worked with a PWA. This discrepancy was found across all work sites (Figure 1).

Multiple linear regression analysis was used to examine whether other factors, besides knowledge about transmission, might predict attitude scores. The results indicate that transmission knowledge scores contributed most (15%) to variation in attitude scores. Gender, education, and self-assessed knowledge were also significant; women, the more highly educated, and those who believed they knew as much or more than others about HIV/AIDS had more favorable attitudes. These factors together explained 23% of the variance in attitude scores (R^2 = .234).

TABLE 3—Workers' Attitudes about People with AIDS (n = 3460)

Attitude Statement	% Who Agree

I would be afraid of getting AIDS if I worked with someone who has AIDS.	23.4

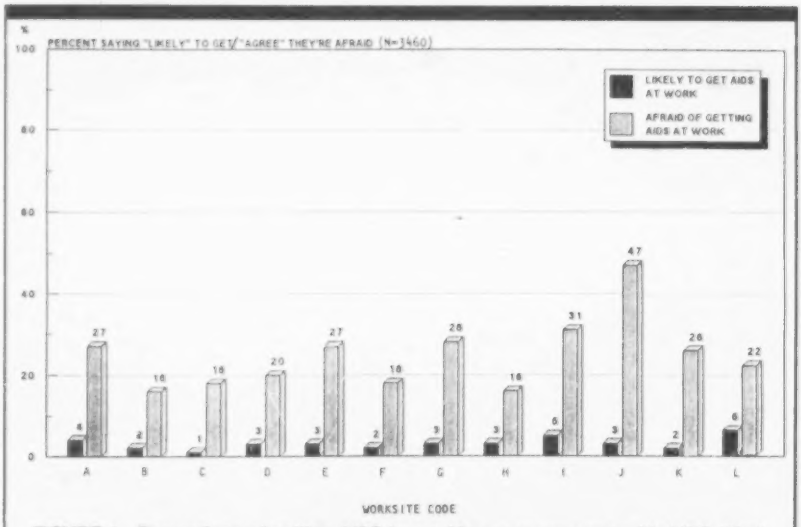

FIGURE 1—Perceptions of getting AIDS by working near someone with AIDS. Work sites are shown in descending order of employee participation in workplace AIDS education; corporate sites are A–F, K, and L; sites G–J are public agencies.

Discussion

The results show that employees having greater knowledge that HIV/AIDS is not transmitted through casual contact are less likely to hold negative views about coworkers with AIDS. Despite this strong relationship, extent of knowledge did not fully explain workplace attitudes. Our findings confirm observations that negative attitudes may persist even when people recognize their own low risk of becoming infected.[3] The volunteered comments suggest that many workers have heard the educational message but are not convinced of its accuracy; they are skeptical about HIV/AIDS information disseminated in the media and by medical experts.[10,13]

Comparisons of work sites in this study show that when employers' educational efforts are minimal, employees are less knowledgeable about HIV transmission through casual contact and less positive in their attitudes about HIV/AIDS in the workplace. Because employees find comprehensive workplace education programs highly informative and a credible source of HIV/AIDS information,[11] these results suggest that such programs should be used to reinforce the knowledge that casual contact is not a source of contagion. Negative and discriminatory attitudes can extend to coworkers who are perceived to be at risk for HIV or who are caring for PWAs.[14] Programs for HIV/AIDS education in the workplace can address these attitudes. By emphasizing the ways HIV/AIDS is *not* transmitted, these programs can reduce fears, thus fostering more tolerant attitudes toward coworkers who are themselves infected or who are caring for someone with HIV/AIDS.[15]

Workplace programs provide an important complement to public health HIV/AIDS education efforts. Private sector initiatives are under way to encourage and assist employers in providing education for employees. Efforts by community agencies and local health departments have made HIV/AIDS education available to workers through their employers. Continued collaboration between public health agencies and private organizations is essential to maintain the consistency, accuracy, and timeliness of information and to promote positive attitudes. At the same time, the efficacy of different types of workplace programs should be assessed. □

Acknowledgments

This research was supported in part by grants from the Robert Wood Johnson Foundation, the Health Services Improvement Fund, the NYNEX Corporation, and the United Hospital Fund of New York. Selected data were presented at the annual meeting of the American Public Health Association, New York City, October 3, 1990. The authors also thank the participating private employers and public agencies for their help in distributing the

questionnaires and the many employees for their time in completing them.

Workplace Compliance with a No-Smoking Law: A Randomized Community Intervention Trial

Nancy A. Rigotti, MD, David Bourne, MD, SM, Amy Rosen, PhD, John A. Locke, MPH, and Thomas C. Schelling, PhD

ABSTRACT

Background. Compliance with state and local laws restricting smoking in public places and workplaces has not been systematically evaluated.

Methods. We assessed workplace compliance with a comprehensive no-smoking law adopted in Brookline, Mass, and tested whether mailing information to businesses increased awareness of and compliance with the law. We conducted a random sample telephone survey of 299 businesses (87% response rate). Self-reported compliance was validated by direct observations.

Results. One year after its adoption, the law was popular with businesses. The prevalance of smoking restrictions, smoking policies, and no-smoking signs was 80%, 59%, and 40%, respectively. One third of businesses banned smoking. Full compliance with the law was low, however, because few businesses posted a copy of their smoking policy as required. The mailing increased employers' awareness of the law. Employers sent the mailing also reported better compliance, but this was not confirmed by direct observations.

Conclusions. The law was popular and contributed to a high prevalence of workplace smoking restrictions. Different interpretations of the law by policymakers and businesses seemed to explain why formal compliance was low. The mailing increased awareness of, but not compliance with, the law. (Am J Public Health. 1992;82:229–235

Introduction

Over the past two decades, states and communities have enacted laws restricting smoking in public places and workplaces at a rapid pace.[1] By 1988, 43 states and over 300 cities and counties had adopted a law limiting smoking in one or more public places.[2] The strictest laws require smoking restrictions at the workplace. As of 1989, laws in 14 states and 297 communities required workplaces to limit smoking.[3,4]

The intent of these laws, often termed clean indoor air laws, is to protect individuals from the discomfort and health hazards of involuntary smoke exposure. The laws may also decrease smoking prevalence by encouraging smokers to quit and discouraging nonsmokers from starting. Whether no-smoking laws will have these effects is not known because they have not been systematically assessed.[2,5] However, laws can be expected to have little impact on air quality or smoking behavior if individuals and businesses do not comply with them. To date, compliance has not been formally evaluated, and implementation has received little attention. Most laws delegate implementation to public health departments but do not fund this activity.[4] Health departments appear to regard the laws as self-enforcing, implying little need for surveillance because high compliance is expected.[2] Enforcement occurs in response to complaints, and a lack of complaints is considered evidence of good compliance and, presumably, reduced involuntary smoke exposure.[2,6] This assumption has not been tested, however.

The passage of a comprehensive no-smoking ordinance in Brookline, Mass, in 1987 provided the opportunity to evaluate workplace compliance with a community clean indoor air law and to test whether employers' awareness and compliance could be improved with intervention. We targeted businesses because the workplace is the primary site outside the home for passive smoke exposure.[7] Surveys indicate that 27% of US businesses and over one third of large corporations have smoking policies, but little is known about how smoking is handled in small businesses, which constitute the majority of American businesses.[1,2,8–11] Furthermore, little is known about how the business community responds to legislation requiring it to adopt smoking policies. The potential for a negative reaction has concerned some policymakers considering no-smoking laws.

We assessed workplace compliance with the Brookline no-smoking ordinance and conducted a randomized controlled trial of town businesses to determine whether a low-cost mailed program of education and surveillance could increase employers' awareness of and compliance with the law. The town's health department, which is responsible for implementing the law, conducted the intervention.

At the time of the study Nancy A. Rigotti was with the Department of Medicine, Massachusetts General Hospital, Harvard Medical School. David Bourne is with the Arkansas Health Department. Amy Rosen is with the Section of General Internal Medicine, Boston University Medical School. John A. Locke, is Director of Public Health, Brookline, MA. Thomas C. Schelling is with the Department of Economics, University of Maryland.

Requests for reprints should be sent to Nancy A. Rigotti, MD, General Internal Medicine Unit, Massachusetts General Hospital, Fruit St., Boston, MA 02114.

This paper was submitted to the journal February 12, 1991, and accepted with revisions June 24, 1991.

We hypothesized that employers sent information would be more aware of what the law required and, consequently, more likely to comply with it.

Methods

Brookline Bylaw

Brookline is a town of 55 062 residents in the Boston metropolitan area.[12] In 1982, there were 1455 businesses and government agencies in Brookline employing a total of 16 758 workers.[13] That year, Brookline became the third Massachusetts community to restrict smoking when the 250-member Town Meeting adopted a bylaw requiring restaurants with 40 seats or more to reserve 25% of those seats for nonsmokers (Bylaw XLI). Five years later, on June 1, 1987, the town meeting passed Bylaw XLII, which restricted or banned smoking in work sites and public places and enlarged restaurant nonsmoking sections to 50% of seats.

The worksite provisions of Bylaw XLII apply to businesses with three or more employees. The law requires employers to establish and post a work-site smoking policy. Employers must provide a nonsmoking working area for all employees. They are allowed, but not required, to designate smoking areas so long as the area does not expose nonsmoking employees or the public to smoke. No-smoking signs must be "conspicuously" displayed in nonsmoking areas. Upon request, a written copy of the policy must be provided to employees or to the director of public health.[14]

Workplace provisions of the bylaw became effective on March 1, 1988. Implementation and enforcement were the responsibility of the health department. The health director used local media, primarily the weekly town newspaper, to inform the public. Food service establishments were formally notified in January 1988 in a license renewal mailing. Inspectors subsequently checked for compliance during routine restaurant inspections. The health department sent no other information to citizens or businesses, except in response to complaints or questions. During the first year, the health department received 11 complaints about work-site smoking and informed those employers about the law. Work-site surveillance to monitor compliance was not done.

Intervention

We obtained a comprehensive mailing list of Brookline businesses from the Massachusetts Department of Employment and Training. The list included all companies using a Brookline address for payment of unemployment compensation taxes. All businesses with five or more employees (n = 535) were included in the trial. Businesses in the smallest category (less than five employees) were excluded because the bylaw applies only to work sites with three or more employees.

The 535 eligible businesses were randomly assigned to one of three groups. The health department mailed an information packet to companies in the two intervention groups in January 1989, 10 months after the law went into effect. No mailing was sent to controls. The packet sent to both intervention groups included (1) a copy of the bylaw, (2) a cover letter from the health director summarizing what the bylaw required of employers, and (3) a sample smoking policy. One intervention group also received a request from the health commissioner to return a written copy of its smoking policy. The estimated cost of preparing and mailing the information packet was $800.

Evaluation

We conducted a telephone survey of Brookline businesses in April 1989, 3 months after the mailing and 13 months after the law became effective. Firms were randomly selected from the 535 businesses in the trial. Of 459 firms telephoned, 53 (11%) could not be reached after four calls and 61 (13%) were not eligible. Interviews were completed in 299 of 345 eligible businesses, a response rate of 87%. Trained interviewers asked to speak to the owner, manager, or employee most familiar with the company's smoking rules. Respondents were informed that the survey was conducted for Harvard University and that data on individual firms were confidential.

The survey instrument, adapted from one we previously developed for a survey of Cambridge, Mass, businesses, contained 34 brief, closed-ended items and required 8 minutes to administer. Respondents were asked about their awareness and opinion of the law, their company's compliance, and their perception of the law's effect on employees, air quality, and costs. To understand how Brookline businesses handled smoking, we asked separate sets of questions about the company's smoking policy for employees, overall rules about smoking, smoking rules in six areas (private offices, shared work areas, public areas, conference rooms, hallways, cafeterias, and employee lounges), and posting of no-smoking signs. Type of business, work-force size, estimated employee smoking prevalence, and respondent's job title and smoking status were also recorded.

To confirm the validity of telephone self-reports, an observer made unannounced visits to all work sites reporting the presence of any one of the three observable outcome measures: a written smoking policy, posted smoking policy, or posted no-smoking sign. Additionally, the observer noted whether no-smoking signs were "conspicuously displayed" as required by law and whether employees or customers were smoking. Direct observations were made in 142 worksites, 48% of our sample. Smoking policies returned to the health department in response to the commissioner's request were reviewed by one rater, who judged whether each complied with the law.

This data collection permitted several separate assessments of compliance with the law: (1) respondents' self-rating; (2) respondents' reports of smoking rules, policies, and signs that constituted an operational definition of compliance; (3) direct observation of policies, signs, and smoking; and (4) analysis of written policies returned to the health department. For the purposes of the study, a business was in full compliance if it posted a written smoking policy at the work site, prohibited smoking in shared work areas and public areas, and posted signs in no-smoking areas.

Data Analysis

We compared the three groups on all endpoints, using chi-square and t tests to analyze the significance of differences in proportions and means.[15] Because the information sent to both intervention groups was very similar, we repeated the analysis, comparing a combined intervention group with controls to investigate the effect of a mailing. There were no major differences between the two intervention groups, and we report results using the combined intervention group. Multiple logistic regression was used to identify factors associated with awareness of the law, opinion of the law, and rules about smoking.[16]

Results

Characteristics of the Sample

Table 1 describes the 299 Brookline businesses surveyed. The average company was small; 73% had less than 20 employees. Nearly half were in service in-

dustries, and employee unions were rare. Employee smoking prevalence, estimated by respondents, was low, as was respondents' own smoking status. There were no significant differences between groups on any descriptive variable. The distribution of business size and type in the sample closely resembles the distribution for all Brookline businesses.[13]

Awareness of the Law

Overall, 36% of businesses were aware of the town's no-smoking law. Companies sent the mailing were more likely to know about the law than were controls, suggesting that the mailing informed businesses (46% vs 18%, $P < .0001$; odds ratio [OR] = 3.88; Table 2). After adjusting, with multiple logistic regression, for potential confounders (business size and type, respondent job category and smoking status), the effect of group designation on awareness was unchanged (OR = 3.82; 95% confidence interval [CI] = 2.11, 6.93). No factor in Table 1 was independently related to awareness.

The 109 businesses aware of the Brookline bylaw were tested on their specific knowledge of six provisions highlighted in the mailing. Businesses correctly answered 64% of the questions, but the proportion of correct responses varied by question (Table 2). Businesses were best informed about the need to post no-smoking signs and ban smoking in public areas. They were least likely to know that providing a smoking area for employees was not required.

Opinion of the Law

One year after it took effect, the law was popular with businesses: 65% of respondents favored the law, 23% were neutral, and only 12% opposed it (Table 2). These proportions did not change when the analysis was limited to respondents aware of the law. The mailing did not influence attitudes about the law. On multivariate analysis, approval of the law was significantly higher in firms with nonsmoking respondents (OR = 4.22; 95% CI = 2.20, 8.17), work-site smoking restrictions (OR = 3.23; 95% CI = 2.23, 6.68), and fewer smoking employees (OR = 1.58; 95% CI = 1.12, 2.23). Approval was unrelated to company size or type.

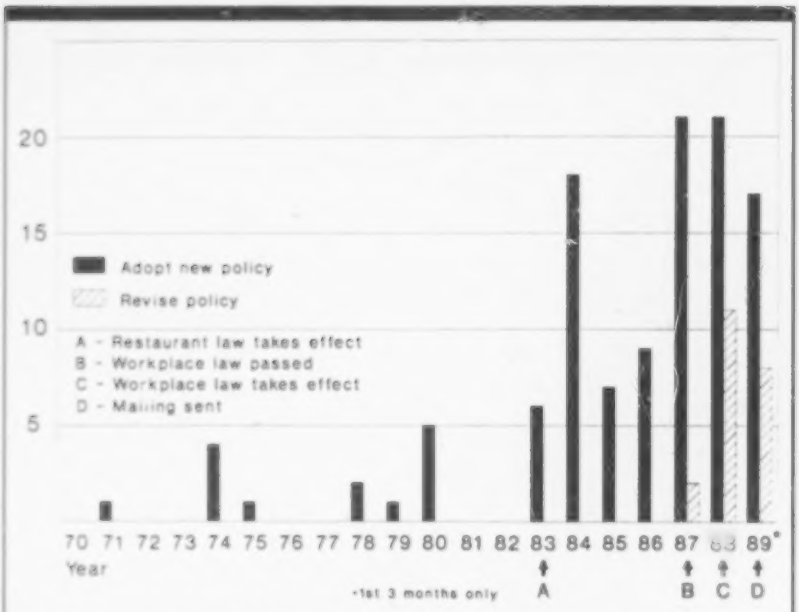
Compliance and Effects of the Law: Managers' Assessment

The 109 businesses aware of the law reported a high level of compliance and few problems. Ninety-five respondents (87%) considered their firm to be in compliance. Only three reported problems in complying; two problems involved employee opposition to smoking restrictions and one involved separating smokers and nonsmokers. Most companies reported that the law did not affect costs (n = 95, 87%) or air quality (n = 78, 72%); the remainder thought air quality had improved. Control and intervention groups did not differ on these questions.

The law also stimulated businesses to take action on smoking. According to respondents, the law prompted 39 firms aware of the law (36%) to adopt or revise a smoking policy. Forty (23%) of 177 companies with smoking policies cited the Brookline law as one reason their policy was adopted, and businesses sent the mailing cited the law more often than did controls (30% vs 10%, $P = .005$). Figure 1 illustrates the number of smoking policies adopted or revised each year among businesses whose managers recalled the date of policy adoption; 114 (64%) of 177 firms with policies could do so. Peaks of activity followed the adoption and implementation of no-smoking laws and the health department mailing. Two thirds (25/38) of firms implementing a policy after the law was adopted (1988 and 1989) were aware of the law.

Compliance: Self-Reports of Smoking Rules, Policies, and Signs

Table 3 displays measures of compliance with the law in all work sites and



Bars represent the number of smoking policies newly adopted (black bars) or revised (shaded bars) in each year, 1970–1989, among businesses who could recall the date of policy adoption. Arrows indicate when local smoking legislation was passed or implemented.

FIGURE 1—Smoking policies adopted or revised by Brookline businesses, 1970–1989.

distinguishes between smoking policies and smoking restrictions. Smoking restrictions were reported by 80% of work sites; 34% banned smoking and 46% restricted it to designated areas. Figure 2 presents the smoking rules for six specific areas. Over 65% of businesses banned smoking in shared work areas, public areas, conference rooms, and hallways. Smoking rules did not differ significantly between companies sent the mailing and controls, although those sent the mailing were more likely to ban smoking in shared work areas (70% vs 58%, $P = .068$).

Respondents were asked separately about their company's smoking policy. Fifty-nine percent replied that their company had a smoking policy for employees at that work site, but only half of these policies were written and only one third were posted at the workplace, as stipulated by law. Forty percent posted no-smoking signs. By our definition, 34 businesses (11%) reported full compliance with the law (Table 3). Companies sent the mailing were more likely than controls to report full compliance, a written smoking policy, and no-smoking signs, although the last difference was not statistically significant.

On multivariate analysis, smoking restrictions were more common in service businesses (OR = 3.48; 95% CI = 1.14, 6.13) and in firms whose top manager did not smoke (OR = 4.74; 95% CI = 2.09, 10.71). Smoking bans were more common in companies with a non-smoking manager (OR = 19.31; 95% CI = 2.56, 145.53) and fewer smoking employees (OR = 1.60; 95% CI = 1.12, 2.29). Restrictions were not independently associated with work-force size.

Compliance: Direct Observations

Direct observations in Brookline businesses confirmed self-reports of no-smoking signs in 98% of firms (119/121), although only 60% of signs were "conspicuously displayed" as required by law. In contrast, we validated few reports of written or posted smoking policies. We observed written policies in 6 of 89 companies reporting them (7%) and posted policies in 5 of 60 companies (8%). Employees often responded to a request for a written or posted smoking policy by pointing to a no-smoking sign.

Table 3 compares control and intervention groups on the validated endpoints of signs and policies. All written and posted policies were observed in businesses sent the mailing, but the number was so small that group differences were not statistically significant. By direct observation, only three Brookline companies (1%) fully complied with the law. Furthermore, a customer was seen smoking in 36% of businesses visited and a smoking employee observed in 14% (Table 3). Firms that banned smoking had significantly fewer smoking customers (15% vs 51%, $P < .0001$) and employees (6% vs 19%, $P = .037$).

Table 4 demonstrates that businesses aware of the law were more likely to comply with it.

Smoking Policies Returned to the Health Department

Half (n = 50) of businesses in the group asked to submit a written smoking policy did so. Nearly all used the demonstration policy provided by the health department. Twenty-nine policies (58%) were in compliance, indicating that smoking was restricted or banned and no-smoking signs were posted. The major reason for noncompliance was the misconception that firms without smoking employees need not have a smoking policy or post signs.

Discussion

This study assessed workplace compliance with a community clean indoor air law 1 year after the law's implementation. It also evaluated a low-cost intervention designed to increase employers' awareness and compliance with the law. Our discussion addresses these questions in order: (1) What was the prevalence of work-site smoking restrictions in Brookline 1 year after the law became effective? (2) Was the law responsible for these restrictions? (3) Did the intervention increase employers' awareness and compliance with the law? (4) What did town businesses think of the law?

1. One year after the law went into effect, the prevalence of work-site smoking restrictions in town businesses was high. Eight of ten firms had some smoking restrictions, one third banned smoking altogether, and two thirds banned smoking in shared work areas, where passive smoke exposure is likely to be highest. Two observations suggest that the situation was more complex, however.

First, there was considerable discrepancy among estimates of smoking policy prevalence. The prevalence of rules about smoking (80%) exceeded that of smoking policies (59%), and self-reported prevalence of smoking policies greatly exceeded that directly observed. Second, we observed customers and employees smoking in some businesses that reported not permitting it. These discrepancies could reflect employers' misrepresentation of their policy, failure to enforce their

policy, or misconception of what is a smoking policy and what the law requires businesses to do. The last two explanations are most likely. Smoking rules were probably not always enforced, and many businesses considered a no-smoking sign to be their written policy or felt no policy was needed because no employee smoked. Misrepresentation is less likely, given good agreement between self-reported and observed estimates of no-smoking-sign prevalence, a more concrete endpoint. It appears that the law was understood differently by policymakers who drafted it and businesses to whom it applied.

Because "smoking policy" was variously interpreted, we consider respondents' reports of "smoking rules" to be a better reflection of the actual prevalence of smoking restrictions in Brookline businesses. We conclude that the prevalence of smoking restrictions is high. Despite this, few Brookline firms complied fully with the law as written. Lack of awareness of the law and misinterpretation of the ordinance probably account for this finding. Nonetheless, it appears that the law achieved much of its intent—reducing exposure to passive smoke. The scarcity of complaints to the health department supports this interpretation but demonstrates that a lack of complaints does not guarantee compliance with a law. The frequency with which smoking was observed in businesses further indicates the limits of complaints as a measure of compliance.

We suggest that differences in practice between large and small businesses account for some of employers' misconceptions about what the law required. While large businesses typically write formal policies to define acceptable employee behavior, small companies (as are most Brookline businesses) appear to make and enforce rules about smoking more informally and communicate them orally to employees, and they may not consider the rules to be policies.[17] Policymakers need to be aware of the practices of small businesses, which constitute the bulk of US companies, in order to draft work-site no-smoking laws that can be readily implemented by small and large firms.

2. To what extent was the Brookline law responsible for work-site smoking restrictions present 1 year later? The law was followed by a dramatic increase in the number of firms adopting smoking policies, and businesses aware of the law had more smoking policies. Companies aware of the law appeared to have been prompted to adopt smoking restrictions; however, without observations from a comparison community, we cannot exclude the possibility that smoking restrictions resulted from concurrent social change. Estimates of work-site smoking policy prevalence in other communities, with which to compare our data, are few. A 4% prevalence of written policies was found in New York City businesses in 1986, prior to a no-smoking ordinance.[18] In contrast, the prevalence of smoking policies and restrictions in Seattle manufacturing companies in 1988 was similar to Brookline, despite Seattle's lack of a work-site no-smoking law. However, Seattle bans smoking in public places and government work sites, and "public acceptance of smoking restrictions is widespread."[19] Although comparisons between surveys require caution, these data suggest that smoking policies may be less

common in communities without laws, but considerable local variability exists. We conclude that smoking restrictions are more common in Brookline businesses than in many communities, due in part to the law.

3. What was the effect of the health department's mailing to businesses? The mailing increased awareness but not compliance with the law. It doubled the number of businesses aware of the law, but it informed fewer than half of town businesses about the law. Awareness is an important endpoint because compliance with a self-enforcing law can be expected only if those subject to it know about it. By itself, the mailing did not clearly increase compliance with the law, and the effect of the mailing was not enhanced by surveillance (e.g., requiring businesses to return a smoking policy to the health department). Surveillance might have been effective had the health department contacted noncompliant businesses it identified. Furthermore, analysis of returned policies provided information valuable for planning subsequent implementation programs. For the health department, major advantages of the intervention were its simplicity and low cost, but these factors also limited its effectiveness. Even with its modest effect, the mailing might be regarded as cost-effective; it cost $14.73 per business informed: $800/[(.46 − .18) × 194 businesses].

4. The law's popularity with employers 1 year after its adoption is an important additional finding. Employers aware of the law reported no adverse effects and did not perceive compliance to be burdensome. Not surprisingly, the law was more popular among respondents who did not smoke and in companies with smoking restrictions and few smoking employees. Managers' strong endorsement of the strictly worded Brookline statute is good news for policymakers in other communities considering no-smoking laws.

Methodologic strengths of this study include the following: we tested the intervention in a randomized controlled trial, assessed outcomes in a large random sample of town businesses, achieved a high response rate to a telephone survey, and validated self-reports by direct observation. Interpretation of study results must consider that this was a study of a single community. The Brookline sample resembles statewide and national distributions of business size, but it has significantly more service and fewer manufacturing businesses than comparison state and national samples.[10,20]

In summary, the Brookline no-smoking bylaw was popular with businesses, increased the adoption of work-site smoking policies, and contributed to a high prevalence of smoking restrictions in town businesses. Although full compliance with the law was low, largely because of misunderstandings in what the law required of businesses, the town's modest implementation effort achieved a good measure of the intent of the legislation. The health department's mailing increased companies' awareness but not compliance with the law. Further implementation efforts could improve awareness, compliance, and enforcement of the law. Nonetheless, the study demonstrates that a local health de-

partment can disseminate information to employers concerning a new requirement with a modest effort. □

Attitudes Toward Genetic Testing of Amish, Mennonite, and Hutterite Families with Cystic Fibrosis

Shelley R. Miller, MS, and Robert H. Schwartz, MD

ABSTRACT

Background. We had the unique opportunity to study families with cystic fibrosis (CF) from an interrelated Amish–Mennonite kindred and from an isolated Hutterite kindred.

Methods. While obtaining blood for DNA linkage analysis to help find the CF gene, we asked family members to answer a questionnaire about attitudes and feelings toward genetic testing. The questionnaire was also administered to families receiving care at the University of Rochester. After DNA-based CF carrier testing was developed, we asked the families whether they wanted to know the results.

Results. Each cultural group felt differently about many issues. Between 31% and 78% approved of CF-carrier testing and 14% to 78% approved of prenatal diagnosis. The majority (59%) of Hutterite parents and siblings were opposed to carriers marrying carriers and most (82%) of the CF families wanted to know the results of carrier testing.

Conclusions. Cultural differences need to be understood before genetic services are offered. Also, most CF mutations and their clinical correlates (phenotypes) will need to be defined. There are as few as three CF mutations in the Hutterite population. It will be possible to offer them the option to choose accurate genetic counseling. It will be difficult to offer genetic services to other populations with more heterogeneous attitudes and many more identified and yet-to-be-identified CF mutations. (*Am J Public Health.* 1992;82:236–242)

Introduction

The cystic fibrosis (CF) gene is on the long arm of chromosome 7. Approximately 80% of the CF mutations at this locus have been identified.[1–3] Direct testing for these mutations and haplotype analysis of other linked DNA markers provide accurate prenatal diagnosis and carrier testing for all at-risk families in which one member has CF. When most of the mutations are identified, it will be possible to identify virtually all CF carriers whether or not they have close relatives with CF. Society must decide under what circumstances genetic testing is advisable and prudent for the general population.[4] Policy development for population screening needs to consider differences among cultural, ethnic, and racial groups.[5]

Between 1976 and 1988, we were introduced to members of an interrelated North American Amish–Mennonite CF kindred (23 related families with 41 CF-affected children) and to members of a genetically isolated Hutterite CF kindred (11 families with 19 CF-affected children). With the help of relatives and genealogists, we implemented a research project with three objectives.

Our first objective was to identify informative families and to obtain blood from volunteers to be used for DNA linkage analyses by collaborating laboratories searching for the CF gene.[6–9] Since these kindreds were from unique cultural backgrounds, our second objective was to try to understand their attitudes, intentions, and feelings regarding various CF-related issues. Later, when carrier testing in at-risk families became reliable and results of haplotype analyses were available, our third objective was implemented. We asked the Amish, Mennonite, and Hutterite CF families (parents of minors and adult siblings) whether they wanted to be informed of their carrier testing results.

We used a questionnaire survey method and compared the responses of Amish, Mennonite, and Hutterite families with a group of 95 CF families who were receiving care at the University of Rochester Medical Center. We also compared our results with those of a similar survey of 346 families in California by Kaback et al.[10] The Amish, Mennonite, and Hutterite responses offer a unique opportunity to better understand CF families from groups that are not well known to the medical world, have a high incidence of CF, and have distinct social views.

Methods

Subjects

The Amish are descendants of the Anabaptist faith of the 1600s.[11] They choose to live simply, in small farming communities, without modern conveniences. They believe in complete obedience to the Bible and its decisiveness and authoritativeness in all disputes.[12]

The Mennonites, also descendants of the Anabaptist movement,[11] have values similar to the Amish, but many are technologically modern and accept, and even promote, higher education.

Members of the Amish–Mennonite kindred are the direct descendants of a common ancestral couple, Christian J.

The authors are with the Department of Pediatrics, University of Rochester Medical Center, New York.

(1766–1828) and Anna F. (1771–1816).[13] Their ethnic background is either Amish or Mennonite. They reside mostly in New York and Ontario, Canada; some Mennonites live in other states, including Alaska, Delaware, Indiana, Louisiana, Michigan, Ohio, and Pennsylvania. Their pedigree has been published.[7]

The Hutterites, also Anabaptists, are a genetic isolate of hard-working, mechanically modernized, religiously devout people who live in communal colonies on farm/ranch settings in Minnesota, North Dakota, South Dakota, Montana, and Washington, as well as in western Canada. The Hutterites have three distinct subgroups (Schmiedeleut, Dariusleut, and Lehrerleut) that originate from the three founding colonies.[14] Formal education is limited and birth control is not allowed. The Hutterites are extremely knowledgeable and productive farmers and animal breeders. Their own roots can be traced in accurate genealogies.[15] The Hutterite CF kindred has been published.[7,8] The parents of 11 CF sibships trace their ancestry to 62 of the 77 founders of the Hutterite population.[8]

Questionnaire

We modeled a questionnaire after one designed by Kaback et al.[10] It was reviewed and edited by a Canadian Mennonite genealogist sensitive to questions that might be offensive. The questionnaire elicited personal, religious, financial, and education data. It also contained questions about general CF knowledge, emotional impact and feelings regarding having a family member with CF, and related family planning issues. Attitudes about the possible use of carrier testing, prenatal diagnosis, and abortion were probed. Thoughts about possible effective treatment and a potential cure for CF were elicited.

Kabeck et al.[10]	211[a]	48	40	11	...

Note. The question asked was, After having a child with CF and learning of your recurrence risk, did you change your planned family size?
[a]Mothers: 40 years of age or less (n = 184) and 41–45 years old (n = 27).

The questionnaire was mailed or hand delivered with an addressed, stamped return envelope. A cover letter asked for the respondents' cooperation by providing their confidential information to a research team working to understand CF. Each person was instructed to complete the questionnaire to the best of his or her ability and to call us collect or write us with any concerns, questions, or comments. The surveyed groups included 118 Amish–Mennonite and Hutterite parents and siblings; 273 Amish–Mennonite and Hutterite aunts, uncles, and cousins; and 171 Rochester parents and siblings. Each family had 1 or more living or deceased individuals who had been diagnosed with CF. Only those who were 18 years of age or older were asked to participate. The responses were anonymously coded and entered into a computer database.

When DNA analysis indicated carrier, noncarrier, or noninformative status of the siblings of CF individuals, we asked the adult siblings whether they wanted to know their carrier status and asked parents whether they wanted to know the status results of their minor children. We also asked the individuals whether they wanted us to inform their doctor of the results.

Results and Discussion

Response

Table 1 is a summary of questionnaire recovery. Table 2 is a summary of questionnaire response according to religious affiliation, sex, and relationship. Of 544 questionnaires, 316 (58%) were returned completed. Nineteen (3%) individuals had moved and left no forwarding address. A significant number of individuals did not return our questionnaire (199, 37%) or returned it unanswered (10, 2%). Possibly, we offended some people by asking personal questions. The length (67 questions) of the questionnaire may have been a deterrent. It is also possible that some individuals did not understand the instructions or questions and did not respond. Because the various religions have specific guidelines regarding such issues as abortion, an individual who differs from those guidelines might decline from responding on his or her own accord or on the advice of church elders.

Finances

We were unable to compare financial data since Hutterites practice a community sharing of goods, work, and life (The Chronicle of the Hutterian Brethren, 1987). When visiting families in the course of obtaining blood for DNA studies, it was our impression that the Amish were the poorest of our groups.

Education

The Hutterites (100%), followed by the Amish (90%), had the least formal education (i.e., less than 12 years of schooling). The majority of Rochesterians (94%), intermarrieds (93%), and Mennonites (72%) had completed high school, and 49% of intermarrieds, 47% of Mennonites, and 42% of Rochesterians had completed college.

Family Size

The average sibship size of an individual with CF was 6.2 in the Amish, 6 in the Hutterites, 3 in the Mennonites, and 2.7 in the Rochesterians. The largest family was found in the Hutterite population (17 children). Two Amish families had 10 children each. The largest Mennonite and Rochesterian families had 7 children each.

Religion/Ethnicity

Amish, Mennonites, and Hutterites are the three surviving Anabaptist groups sharing common beliefs about adult baptism, nonresistance, and simple living.

Members of the intermarried group were, by birth, Protestant, Catholic, or

Note. CF = cystic fibrosis. The question asked was, How physically and emotionally demanding has caring for your child/children (sibling/siblings) been for you?

nondenominational; they married Amish or Mennonites but did not practice either of those religions.

The Rochester population consists primarily of those of Protestant (46%) and Catholic (43%) faiths; some are Jewish, some are Episcopalian, and some are Jehovah's Witnesses.

General CF Knowledge

Table 3 shows the percentages of individuals who correctly answered general CF questions regarding recurrence and carrier risks. Among parents and siblings, Mennonites (87%), Rochesterians (75%), and Hutterites (72%) were the most knowledgeable about recurrence risk to parents who have already had a child with CF. The Mennonite and Rochester parental responses closely resemble the responses among parents (85.9% correct) in the study of Kaback et al.[10] Those parents with the most formal education (Mennonites, Rochesterians, and intermarrieds) were the most knowledgeable. Except for the Amish, siblings were strikingly knowledgeable when asked this same question about their parents' recurrence risk.

Table 3 also indicates the percentage of correct responses regarding unaffected sibling carrier risk, a conceptually difficult question. It has been our experience that even some of the doctors and nurses who have helped us have incorrectly answered this question. Overall, 88% of parents and 75% of siblings answered incorrectly. Siblings were more knowledgeable than their parents when asked the unaffected sibling carrier risk. This is not surprising, since this statistic has more relevance for siblings. Again, those populations (Mennonites and Rochesterians) with more formal education were more knowledgeable.

Family Planning

Table 4 indicates that after having a child with CF and learning of their recurrence risk, the majority of Mennonite (53%) and Hutterite (61%) parents said they changed their planned family size, as did 45% of Rochesterians. The majority (72%) of Amish were uncertain about this matter.

Except for the Amish, our observations support the findings of Kaback et al.: having a child with CF and learning of the recurrence risk (correct or incorrect) has a major impact on future reproduction. Of those families who changed their planned family size, the majority (80% of Mennonites, 75% of Hutterites, and 100% of Rochesterians) had no more or fewer children than they would have liked. Although the numbers are small (n = 7), the uncertainty (72%) in the Amish is difficult to interpret. It may reflect a confusion with the question or a personal reflective uncertainty.

[a]One family wanted only their doctor to have the results.

CF-Related Stress

Table 5 indicates that the majority of each group of parents and siblings found their caretaking responsibilities to be slightly to moderately stressful. The majority of all of the groups found that caring for a child or sibling with CF had been slightly stressful. More siblings than parents found there was no stress, which probably indicates that parents are primarily responsible for child care.

Caring for children with CF can be physically and emotionally demanding. In our society, stress is a subjective factor that induces bodily or mental tension. It has both positive (motivation) and negative (fatigue, irritability) qualities. The most stressed groups were the Mennonite and Rochester parents. The Mennonites and Rochesterians, with their more modernized life-style and city dwelling, may have less emotional and physical support

Note. The question asked was, Do you think carriers should be allowed to marry carriers?

available to them and thus feel more stress than the traditional rural Amish and Hutterites.

Carrier Testing

Table 6 indicates that more than half of Amish (58%), Mennonite (53%), Hutterite (54%), and Rochester (78%) parents approved of carrier testing prior to its actual availability. Among siblings, the majority of Mennonites (67%) and Rochesterians (79%) approved, while the majority of Amish (62%) and Hutterites (87%) did not approve. The majority of aunts and uncles approved of CF-carrier testing.

The younger generation has mixed feelings. The older generation may be experiencing the well-known phenomenon of parents wanting their children to have a better life than they have had, including having healthy children.

Prenatal Diagnosis

Table 6 also indicates that the majority of Mennonites (54%), Rochesterians (77%), and intermarrieds (78%) approved of prenatal diagnosis for CF, while more Amish (86%) and Hutterites (79%) did not approve or were uncertain.

Rochesterians and the population of Kaback et al., most similar in life-style, were also most similarly aligned in their approval of prenatal diagnosis. The Amish and Mennonites, from the same religious roots, single themselves out as having the most unfavorable and uncertain reaction to prenatal diagnosis. Prenatal diagnosis may be more morally and religiously objectionable to this group.

Carrier Testing Results

Table 7 shows that the majority of Mennonites (88%) and Hutterites (82%) clearly wanted to know their carrier testing results. This may reflect their desire to have some control over pregnancy outcome—at the time of mate selection. Members of one Mennonite family wanted the results to be given only to their doctor.

The Amish were equally split between wanting to know (40%) and not wanting to know (40%), with one family providing no response. The sample size is too small to draw conclusions. Considering that some families wanted to know their results and considering their high degree of uncertainty as to whether carriers should be allowed to marry carriers, it is possible that some Amish families might use their carrier results to influence the mate selection of their carrier children.

Carriers Marrying Carriers

Table 8 shows that the majority of Hutterites (59%) did not think CF carriers should marry CF carriers. Rochesterians were the group most (51%) approving. This question generated no response or uncertainty in a majority of Amish and in almost half of the Mennonites and intermarrieds. The majority of Amish and Mennonite parents were uncertain about whether carriers should be allowed to marry carriers.

It appears that the Hutterite parents might use carrier testing information (Tables 6 and 7) to discourage carriers from marrying carriers. Perhaps their self-taught skills and knowledge of plant and animal reproduction carry naturally into the practice of their own reproductive lives and they are able to avoid certain marriages if they are at risk for having a child with a genetic disease. The Hutterites keep extensive records of their genealogy and know the relationship of each young courting couple. Rochesterians, approving of carrier testing and of carriers marrying carriers, might use their carrier knowledge to avail themselves of prenatal diagnosis. It is unclear whether the Amish and Mennonites would intervene in the marital selections of their children.

Abortion

Table 9 shows that Amish and Hutterite parents (100%) and siblings (100%) are opposed to or uncertain about the elective abortion of CF-affected fetuses. Mennonites were almost evenly split between approving (37%), disapproving (35%), and being uncertain (28%). More than half of Rochesterians (56%) and intermarrieds (71%) approved.

The Amish and Hutterites are most opposed to abortion under any circumstances. These two groups are the most socially, financially, and geographically bound to their church, colony, and community, and they are the least formally educated. The Mennonites, Rochesterians, and intermarrieds were more lenient in their views about abortion, with the Rochesterians more lenient than the Mennonites. These three groups favored elective abortion if a woman wants one and/or only in specific cases. A surprising finding was the break with tradition of a small group of Amish aunts and uncles who approved of elective abortion at a woman's request.

Subsequent Pregnancies

Table 10 indicates that our research supports the findings of Kaback et al. that

TABLE 9—Attitudes Toward Abortion

Note. CF = cystic fibrosis. The question asked was, Which statement best reflects your attitude? A. A woman should be able to have an abortion if she wants one. B. A woman should be able to have an abortion only in specific cases. C. A woman should not be able to have an abortion under any circumstances.

TABLE 10—Subsequent Pregnancies

		Families with Cystic Fibrosis in Last Child (%)
Amish	...	...
Mennonite	50	(6/12)
Hutterite	71	(5/7)
Rochester	73	(29/40)
Total	68	(40/59)
Kaback et al.[10]	65	(119/183)

Note. The question asked was, After the diagnosis of cystic fibrosis was made in your child, was that child the last child in your family? Parents responded as a couple.

after a CF diagnosis was made in a child, many families (68%) stopped having children and the child with CF tended to be the last child born in a sibship of two or more children. Conclusions about the Amish parents could not be made. Some of these families were uncertain about when the CF diagnosis was made and how it coincided with future pregnancies. In some cases, additional children had already been born before the diagnosis was made. One intermarried parent was counted in the Mennonite group with his Mennonite wife.

It is not surprising that the physical, emotional, and financial challenges of having a child with CF cause families not to risk having another child with CF and to stop having children, healthy or otherwise. This behavior occurred prior to the availability of reliable prenatal diagnosis.

Treatment

When asked whether they thought a totally effective treatment, capable of stopping all symptoms, would be found in the next 5 years, the Amish were the most optimistic and the Hutterites were the most pessimistic. The responses, in order of optimism, were as follows: Amish, 52% (n = 29); Rochesterians, 48% (n = 79); Mennonites, 44% (n = 151); intermarrieds, 39% (n = 28); and Hutterites, 24% (n = 29).

Cure

When asked whether a cure would be found within the next 5 years, Rochesterians were the most optimistic and Hutterites were again the most pessimistic. The responses, in order of optimism, were as follows: Rochesterians, 59% (n = 79); Mennonites, 54% (n = 151); Amish, 52% (n = 29); intermarrieds, 39% (n = 28); and Hutterites, 34% (n = 29).

Conclusion

The fury of CF research and discoveries has made genetic testing a valuable option to many at-risk families. When considering genetic testing of populations, it is important to identify differences in prevalences of various CF mutations within and between cultural, ethnic, and racial groups. Our collaborators and others have begun to report these differences.[9,16,17] In addition, any phenotypic differences associated with these mutations must be defined in order to provide accurate counseling.[18–20] Likewise, before genetic testing and counseling services are offered on a voluntary or routine basis, it is also important that cultural differences in beliefs, attitudes, feelings, and behavior be identified and understood.

In our study of Amish, Mennonite, Hutterite, and Rochester families with CF, 31% to 78% approved of CF-carrier testing; 14% to 78% approved of prenatal diagnosis. Being opposed to abortion and/or the abortion of CF-affected fetuses did not deter some from considering prenatal diagnosis. Each cultural group felt differently about many issues.

The majority (59%) of Hutterite CF parents and siblings were opposed to carriers marrying carriers, and most (82%) of the CF families wanted to know the results of carrier testing. By haplotype analysis, only three CF mutations have been found in the Hutterites.[9] One of these is the common ΔF508 deletion. When the other two mutations are defined, it will be possible to offer the Hutterite population accurate genetic counseling. For other populations, where many more identified and yet-to-be-identified CF mutations exist, accurate counseling and testing will be more difficult. □

Acknowledgments

This work was supported in part by National Institutes of Health Grant AM34917, Integrated

Genetics, and the Rochester Chapter of the Cystic Fibrosis Foundation.

We wish to thank Lorraine Roth for her help in genealogy and for her wisdom about her people—the Amish-Mennonites. Richard A. Doherty, MD, provided an empathic academic atmosphere in which this research was encouraged. Ken Morgan, PhD, and Mary Fujiwara, MS, our Canadian colleagues, were pivotal in helping us to understand and study the Canadian Hutterites. Ann Mc Mullen, RN, MS, provided liason with the Rochester CF families. We also wish to thank Jeff Shapiro for his journalistic guidance and enthusiasm and Janice Cosgriff for her weekends of dedication. Special thanks are also extended to Katherine Klinger, PhD, Paul Watkins, PhD, and Pat Stanislovitis, MS, who provided ongoing analyses of carrier status as new techniques evolved.

The Accuracy of Medicare's Hospital Claims Data: Progress Has Been Made, but Problems Remain

ABSTRACT

Background. Health care databases provide a widely used source of data for health care research, but their accuracy remains uncertain. We analyzed data from the 1985 National DRG Validation Study, which carefully reabstracted and reassigned ICD-9-CM diagnosis and procedure codes from a national sample of 7050 medical records, to determine whether coding accuracy had improved since the Institute of Medicine studies of the 1970s and to assess the current coding accuracy of specific diagnoses and procedures.

Methods. We defined agreement as the proportion of all reabstracted records that had the same principal diagnosis or procedure coded on both the original (hospital) record and on the reabstracted record. We also evaluated coding accuracy in 1985 using the concepts of diagnostic test evaluation.

Results. Overall, the percentage of agreement between the principal diagnosis on the reabstracted record and the original hospital record, when analyzed at the third digit, improved from 73.2% in 1977 to 78.2% in 1985. However, analysis of the 1985 data demonstrated that the accuracy of diagnosis and procedure coding varies substantially across conditions.

Conclusions. Although some diagnoses and all major surgical procedures that we examined were accurately coded, the variability in the accuracy of diagnosis coding poses a problem that must be overcome if claims-based research is to achieve its full potential. (*Am J Public Health.* 1992;82:243–248)

Introduction

Administrative health care databases provide an increasingly accessible and widely used source of data for health care research.[1–10] However, the accuracy of hospital discharge data remains uncertain. Studies conducted in the 1970s found that the coding of nonclinical data, such as age, gender, and dates of admission and discharge, was highly accurate but that diagnoses and procedures were less reliably coded.[11–13] Recent studies continue to raise questions about the accuracy of diagnostic coding.[14–16]

The National Diagnosis Related Group (DRG) Validation Study, which provided the most comprehensive recent assessment of the accuracy of hospital discharge data, found an overall error rate of 20.8% in DRG assignment.[17] However, because many individual DRGs include diverse clinical conditions,[18] the findings could not be generalized to the coding of specific diagnoses or procedures. Also, the published results could not be directly compared with those of the Institute of Medicine (IOM) studies of 1977 and 1980, even though both the National DRG Validation Study and the IOM studies used similar methods. We reanalyzed the data from the National DRG Validation Study to address these issues.

Methods

Record Selection and Reabstraction

The methods of the National DRG Validation study have been described in detail elsewhere.[17,19] Briefly, the Office of the Inspector General, US Department of Health and Human Services, randomly sampled hospitals from each of three bed-size strata, excluding specialty hospitals and those in states not using prospective payment during the study period. In the second stage, a random sample of 30 Medicare discharges between October 1, 1984, and March 31, 1985, was selected from each of the 239 hospitals and copies of the medical records were requested. Of the 7076 discharges selected, 7050 charts (99.6%) were obtained. As previously reported, the sample accurately represented the population of all Medicare beneficiaries in prospective payment system jurisdictions.[17] Accredited records technicians, blinded to the coding in the original records, reviewed the medical records, selected the supportable diagnoses and procedures, and translated them into International Classification of Diseases, Ninth Edition, Clinical Modification (ICD-9-CM) numeric codes. Reviewers adhered strictly

TABLE 1—Frequency with Which Reabstracted Principal Diagnoses Agree with the Computerized Abstract in the 1977 Institute of Medicine study of National Hospital Discharge Survey Data (IOM) and the 1985 Office of the Inspector General National DRG Validation Study (OIG)

Diagnosis (ICD-9-CM code)	Agreement of Hospital Abstract Principal Diagnosis: With IOM Reabstract (1977)	With OIG Reabstract (1985)	% Change, 1977 to 1985
Infectious and parasitic diseases (001-139)	62.6	65.4	2.8
Neoplasms (140–239)	57.4	84.3	26.9
Endocrine, nutritional, and metabolic diseases (240–279)	71.3	81.1	9.8
Diabetes (250)	65.7	88.2	22.5
Diseases of the blood and blood-forming organs (280–289)	58.2	64.7	6.5
Mental disorders (290-313)	80.8	69.6	−11.2
Diseases of the nervous system and sense organs (320–389)	85.7	91.4	5.7
Diseases of the circulatory system (390–349)	74.3	83.1	8.8
Cerebrovascular accident (438)	61.2	77.9	16.7
Congestive heat failure (428)	73.9	84.3	10.4
Diseases of the respiratory system (460–519)	73.6	65.8	−7.8
Acute bronchitis (466)	66.4	52.7	−13.7
Diseases of the digestive system (520–579)	81.0	81.7	0.7
Cholelithiasis (574)	85.8	89.0	3.2
Diseases of the genitourinary system (580–629)	78.1	83.7	5.6
Diseases of the skin and subcutaneous tissue (680–709)	73.0	78.5	5.5
Diseases of the musculoskeletal system (710–739)	71.3	82.5	11.2

Note. The table shows the frequency (weighted percent), within each diagnostic group, with which the individual *three-digit* code on the original computerized abstract agrees with the individual three-digit code on the reabstracted record. For instance, within "Neoplasms," if the original abstract listed as the principal diagnosis the code 162.2, "malignant neoplasm of the main bronchus," and the reabstracted record listed a primary diagnosis of 162.3, "malignant neoplasm of the upper lobe, bronchus or lung," this would be tabulated as showing agreement, even though the four-digit codes differ.

to ICD-9-CM and Uniform Hospital Discharge Data Set coding rules. The ICD-9-CM codes were entered into the GROUPER program to assign the proper DRG. A second blinded recoding of 5% of the sample by different medical records technicians, conducted to determine the reliability of the reabstraction process, revealed no significant discrepancies in DRG assignment (agreement = 0.95, $\kappa = 0.86$, $Z = 2.12$).

Comparison with Institute of Medicine Study

We chose to compare our data with those from the IOM study of the accuracy of the National Hospital Discharge Survey (NHDS) data[13] rather than the IOM study of Medicare data[12] because the sampling methods of the former were similar to those of the National DRG Validation study, and the 1977 NHDS discharge abstract was more similar to current discharge abstracts than were the Medicare abstracts of the 1970s. Although the earlier study used ICDA-8 rather than the currently employed ICD-9-CM, the broad diagnostic groupings we present are identical. To assess overall agreement, we determined the proportion of all reabstracted records that had the same principal diagnosis coded on the original record and on the reabstracted record at the specified level of truncation (third or fourth digit). We used the same method to determine overall agreement for procedures (except that truncation was at either the second or third digit). To assess agreement within NHDS diagnostic categories, we determined the proportion of reabstracted records with a specified principal diagnosis that had the same principal diagnosis coded on the original record. Calculations were weighted according to our sampling weights to ensure comparability with the IOM study.

Diagnosis- and Procedure-specific Analyses of Coding Accuracy

To analyze the accuracy of coding with respect to specific procedures and diagnostic conditions, three clinicians familiar with both health services research and ICD-9-CM coding rules aggregated codes into clinically distinct groups of diagnoses and procedures such as might be used to select patient cohorts for studies of the outcomes of medical hospitalizations or surgical treatments. Within each diagnosis and procedure group, we compared the codes as recorded on the computerized abstract submitted to the Health Care Financing Administration (original record) with the codes as determined by the Office of the Inspector General (OIG) reabstraction of the medical record (reabstracted record).

We evaluated the coding accuracy of the current data using the concepts of diagnostic test evaluation.[20] Within this framework, we consider the reabstracted record to be the "gold standard" for defining the presence of a diagnostic condition or the performance of a particular procedure. Thus, the sensitivity (true positive rate) is the conditional probability that a diagnosis (or procedure) within the specified group was coded on the original record given that a diagnosis (or procedure) within the specified group was actually present on the reabstracted record. Specificity (true negative rate) is the conditional probability that a diagnosis or procedure was not present on the original record, given that is was not coded on the reabstracted record. Positive predictive value is the conditional probability that a diagnosis (or procedure) was actually present on the reabstracted record, given that it had been coded on the original record. To calculate 95% confidence intervals for sensitivity and positive predictive value, we used an exact method based on the two-tail binomial test.[21] For the analyses presented in Tables 2 and 3 we calculated the point estimates using both weighted and unweighted data. Because the results were very similar and the use of the unweighted data allowed us to calculate confidence intervals, we present our findings based on the unweighted data.

TABLE 2—Prevalence and Accuracy of Diagnoses on the Computerized Abstract Prepared by the Fiscal Intermediary, Compared with the Office of the Inspector General (OIG) Reabstracted Data (n = 7050 cases)

Diagnosis (ICD-9-CM code)	Diagnosis in Any Position			Diagnosis in Principal Position

Hip fracture (820–820.9)	125 (1.8)	0.96 (.91, .99)	0.94 (.89, .98)	119 (1.7)	0.97 (.92, .99)	0.96 (.91, .99)

[a]Count (%) with specified codes present on the reabstracted (OIG) record.
[b]Sensitivity is the proportion of all cases with a given code (or range of codes) present on the OIG reabstracted record that were found to have a code within the same range on the bills submitted to HCFA on behalf of the hospitals by the Fiscal Intermediary.
[c]Positive predictive value is the proportion of cases with a given code (or range of codes) present on the record submitted to HCFA by the Fiscal Intermediary that were confirmed on the OIG reabstracted records.
[d]The 95% confidence interval is given in parentheses.

Results

Comparison of 1977 with 1985

Overall, the percentage of agreement between the principal diagnosis on the reabstracted record and the original hospital record when codes were truncated at the third digit was 78.2% in 1985, compared with 73.2% in 1977. When codes were truncated at the fourth digit, we found 71.5% agreement, compared with 63.4% in the earlier study. For principal procedures, agreement at two digits was 76.2%, identical to the 76.2% reported in 1977, and agreement at three digits was 73.8% in 1985, compared with 71.4% in 1977. When grouped by principal diagnosis into the diagnostic categories used in the NHDS, the percentage of agreement between reabstracted records and original records varied widely in each study (Table 1). In all but two diagnostic groups (mental disorders and diseases of the respiratory system), the accuracy of the coding of principal diagnosis improved between 1977 and 1985, with the greatest percentage improvement occurring in the coding of neoplasms.

Accuracy of Diagnosis and Procedure Coding

Tables 2 and 3 present relevant measures of coding accuracy for selected diagnoses and procedures according to whether the condition or procedure was coded in the principal position or in any position on the discharge abstract. We present two measures of the accuracy of hospital coding: sensitivity, the proportion of cases with a given code present on the reabstracted record that were correctly coded by the hospital; and positive predictive value, the proportion of cases assigned a given code by the hospitals that the reabstraction process confirmed. Specificity is not presented because it was over 94% (generally over 99%) for all conditions and can be calculated from the data presented.

The accuracy of diagnosis coding varied widely (Table 2). When position on the discharge abstract was ignored, sensitivity ranged from a low of 0.58 for peripheral vascular disease to a high of 0.97 for breast cancer. The positive predictive value for the selected conditions also varied widely, from 0.53 for peripheral vas-

[a]Count (%) with specified codes present on the reabstracted (OIG) record.
[b]Sensitivity is the proportion of all cases with a given code (or range of codes) present on the OIG reabstracted record that were found to have a code within the range on the bills submitted to HCFA on behalf of the hospitals by the Fiscal Intermediary.
[c]Positive predictive value is the proportion of cases with a given code (or range of codes) present on the record submitted to HCFA by the Fiscal Intermediary that were confirmed on the OIG reabstracted records.
[d]The 95% confidence interval is given in parentheses.

cular disease to 0.94 for hip fracture. A similar range in coding accuracy was found when the analysis was restricted to the principal diagnosis.

The coding of major procedures was substantially more accurate than the coding of most diagnoses (Table 3). Sensitivity, when position was ignored, ranged from a low of 0.88 for cardiac catheterization to over 0.95 for 10 of the 15 procedures. Positive predictive value, for principal procedures, ranged from a low of 0.89 for cardiac catheterization to over 0.99 for seven procedures.

Discussion

Recent published research on the accuracy of Medicare's hospital discharge data has focused on reimbursement issues and has reported findings in the aggregate rather than for specific clinical conditions.[17,22] The National DRG Validation Study reported 79.2% agreement in DRG assignment for discharges in 1985.[17] We found similar overall accuracy at the three-digit coding level for principal diagnoses in 1985. However, these aggregate results obscured substantial variations in the coding accuracy of individual conditions and procedures. Several medical conditions, such as hip fracture, acute myocardial infarction, and most cancers, were accurately coded, as were virtually all major surgical procedures. Many clinical conditions, however, were coded with limited accuracy.

Several limitations of our study must be kept in mind. First, relatively small numbers of records were available for use in assessing the coding of many individual conditions. Consequently, some of our estimates have wide confidence limits and it would be inappropriate to assume that the coding of conditions that we did not examine is either poor or excellent. Second, our study relied on data from the last 3 months of 1984 and the first 3 months of 1985, and recent work by Carter et al. suggests that coding accuracy has improved since 1985.[22] Reabstraction of a national sample of records by the SuperPRO revealed that the proportion of cases on which the hospital and SuperPRO agreed on the weight of the DRG improved from 77% in 1985 to 86% in 1988.[22] However, because aggregate results reveal little about the coding of individual conditions, and the relative accuracy of coding across individual conditions is unlikely to have changed substantially, our findings should prove useful even to researchers who plan to use only the more recent data.

The most important limitation of our study, however, is that the clinical accuracy of the coding cannot be directly in-

ferred from our findings. Like previous studies, the National DRG Validation Study was designed to test the accuracy with which hospitals adhered to coding rules,[23] rather than to assess the validity of the claims data as a source of information on patients' health status or medical treatments. Consequently, the findings we report do not directly answer the two major clinically relevant questions of whether a specific condition present *in the patient* was coded on the computerized abstract (sensitivity) and whether specific conditions coded on the abstract actually were present *in the patient* (predictive value positive). This distinction between coding conventions and clinical status may explain the low accuracy with which some medical conditions are coded. A diagnosis may have been present but not recorded on the computerized abstract either because there were five more serious conditions present or because the condition was judged not to contribute to the care provided to the patient.[23] If a condition is coded by one abstraction team but not the other, it seems likely that the condition was documented in the patient's chart but that the two abstractors disagreed about whether it should be recorded among the listed diagnoses. Such misclassification could lead to an underestimate of both the sensitivity and the positive predictive value of the coded diagnoses.

This distinction between coding rules and clinical status also provides the basis for a caveat about our finding that the coding of acute myocardial infarction was relatively accurate. Although their study was based on a small sample of hospitals and was conducted prior to the implementation of the prospective payment system, Iezzoni et al. found that 9% of cases coded as acute myocardial infarction at nonteaching hospitals and 42% of cases at teaching hospitals did not meet clinical criteria for this condition.[14] New rules have been implemented specifically to address the limitations of myocardial infarction coding, but the proper clinical interpretation of many coded diagnoses will remain uncertain until clear-cut clinical criteria for their use are established and promulgated. Surgical procedures, because of the precision with which they are defined and the accuracy with which they are coded, pose less difficulty in interpretation.

What are the implications of our findings? One common use of administrative databases is in research comparing outcomes across individual hospitals or among classes of hospitals.[7,24] Our demonstration of variability in condition-specific coding accuracy and previously reported differences across types of hospitals in aggregate coding accuracy[14,16,17] underline the importance of interpreting claims-based hospital comparisons with caution. However, the potential value of administrative health care data has been demonstrated in follow-up studies based on more complete and accurate data,[25,26] and it justifies the increasing support for continued, if cautious, pursuit of claims-based studies.[8]

A second major use of claims databases is in population-based studies of the outcomes of specific conditions or treatments.[8–10] The major advantages of such claims-based studies are their relative efficiency and their potential to avoid the possible selection bias inherent in institution-specific or other convenience samples. From a clinical perspective, such studies may offer valuable information about the short- and long-term outcomes of common treatments and conditions in the general population.[10,27–29] Our findings demonstrate that major surgical procedures and medical conditions that are accurately coded, such as hip fracture and cancers, can be reliably identified through the claims data. However, for clinicians to apply the findings of claims-based research to help their patients understand the likelihood of relevant outcomes of specific treatments, the study population must be stratified according to the full range of clinical characteristics that may influence the outcome of treatment, including age, gender, severity of illness, functional status, and comorbidity.[29] The current level of coding accuracy and diagnostic precision is clearly insufficient to achieve the level of detail that most clinicians would seek in such studies.

Further improvements in the precision and accuracy of hospital coding would facilitate health care research. However, achieving a high level of accuracy for all conditions will clearly require substantial effort and attention to the many causes of inaccurate coding that have long been recognized.[17,30–32] In the short term, two steps should be considered to help overcome the constraints imposed by the variable accuracy of diagnosis coding and the uncertain clinical implications of diagnostic codes. First, studies similar in scope to the National DRG Validation study should be repeated at regular intervals and should report not only coding accuracy—the degree to which hospitals adhere to Uniform Hospital Discharge Data Set coding rules—but also the clinical accuracy of the coding. Second, a mechanism should be established to facilitate investigators' access to medical records for cases identified through the claims data. Chart review would not only ensure proper case definition, but would also allow precise case-mix measurement and accurate description of the specific interventions received by each patient.

The Medicare administrative databases are a valuable resource collected at great expense. Our findings show that some conditions may currently be studied using the claims data alone and that modest progress has been achieved in improving the accuracy of diagnostic coding. In the long run, improving overall accuracy would enhance claims-based research. In the short run, the implementation of steps to supplement the currently available data would provide investigators with an even more powerful tool for use in evaluating the outcomes of hospital care. □

Acknowledgments

Support for this study was provided by the Agency for Health Care Policy Research (grant R18 HS05745) and the National Institute of Aging (grant R01.AG07146-01).

For their assistance with this project, the authors are indebted to Cathaleen A. Ahern, Barry L. Steeley, and Jane C. Tebbutt of the DHHS Office of Inspector General; Patricia E. Brooks, Anne B. Fagan, and Barton C. McCann of the US Health Care Financing Administration; Penni I. St. Hilaire of the US Public Health Service; Annette M. Delaney, Laurie H. Moore, Joseph S. Yarmus, and their staff at Baxter Health Data Institute; and John R. Boyle and Walter P. Weaver of the DHHS Office of the Assistant Secretary of Management and Budget. We would also like to thank John E. Wennberg, Wayne Ray, and an anonymous reviewer for their helpful comments. □

Cancer Anxiety and Attitudes toward Mammography among Screening Attenders, Nonattenders, and Women Never Invited

ABSTRACT

A mailed questionnaire survey was conducted among the following groups: 179 women who screened false positive at a free mammography screening; a random sample of 250 women who screened negative; 670 nonattenders of the screening; and a random population sample of 250 women who lived in another city and were not invited, but were otherwise comparable. The most frequently reported reason for nonattendance was not having the opportunity. Furthermore, only 18% of the nonattenders reported anxiety about breast cancer compared with 33% of the population sample ($P < .05$). Ninety-nine percent of the women who attended indicated a positive attitude toward mammography that had not been adversely affected by screening experiences. (*Am J Public Health.* 1992; 82:249–251)

Inger Torhild Gram, MD, and Suzanne E. Slenker, PhD

Introduction

Mammographic screening has been the only effective means of reducing breast cancer mortality.[1–5] However, several authors have questioned the magnitude of this mortality reduction and called attention to potential adverse effects of mammography screening.[6–11] The few available studies of this topic indicate that most women cope well with the screening situation and its consequences.[12–15] The purpose of this study was to investigate breast cancer anxiety and attitudes toward mammography among screening attenders, nonattenders, and women never invited to participate.

Methods

A free mammographic screening was offered to 4323 women aged 40 or older as part of the Third Tromsö Study conducted in Tromsö, Norway, in 1986 and 1987.[16] Altogether, 3653 (85%) accepted the mammogram. A total of 193 (5%) of the screenees required further evaluation, which for 40 subjects included a biopsy. Details of the screening and case-finding procedures are given elsewhere.[17]

Of the 193 women requiring further examination, only those 179 who were not diagnosed with breast cancer were eligible for the present study, and they constituted the false positive (FP) group. The three other groups in this study were a random sample of 250 women who screened negative (SN), the 670 nonattenders, and a random population sample (PS) of 250 women living in the nearby city of Harstad. The latter women were not invited to the screening but were otherwise comparable to the Tromsö women and thus served as the reference group.

A questionnaire concerning perceptions about mammography, frequency of breast self-examination, and anxiety about having breast cancer was designed, pilot tested, and then mailed to all study subjects in 1987 after the mammography screening was completed. A reminder questionnaire was sent out to all nonrespondents. Among nonattenders, 120 women (18%) were excluded from the study (8 had died, 17 had breast cancer, 32 had moved, and 63 were unknown at address). The response rate among the remaining women was 84% among the SN group ($n = 209$), 89% among the FP group ($n = 160$), 38% among the nonattenders ($n = 210$), and 66% among the PS group ($n = 164$). Subjects were classified as residing in rural areas if their travel distance to the mammography unit was about 30 minutes or more.

Statistical analyses of the data were performed using the Pearson chi-square statistic for categorical data and Student's t test for continuous data.[18] The analyses were performed using SAS programs.[19]

Results

The median age of the study population was 46 years (range of 40 to 61 years), and the mean years of schooling was 10. Risk factors for breast cancer—such as a family history, age at menarche, age at

**Statistically significant, $P < .001$.

first birth, and prior breast biopsy—did not vary by group. Data are not shown for these factors.

The nonattenders were more likely to live in rural areas than the attenders ($P < .001$); they were also more likely to be unemployed and never to practice breast self-examination than the PS group ($P < .05$). Thirty-two of the nonattenders had had a recent mammogram. This was considered a legitimate reason for nonattendance, and these women were removed from the analysis. The remaining women (n = 178) reported that not having the opportunity (39%); not wanting to participate in the Tromsö Study (15%); fear of X-rays (13%); concern about painful examination (4%); not receiving a personal invitation (4%); fear of discovering breast cancer (3%); and the potential of having a male examiner (3%), were the reasons for nonattendance. Some women gave more than one answer, 22% did not answer, while altogether 14% of the women claimed, without giving further explanations, that none of the listed factors was the rationale behind their nonattendance.

Table 1 shows that both the SN group and the nonattenders reported significantly lower breast cancer anxiety at follow-up than the PS group ($P < .05$). The nonattenders also recalled being less anxious about breast cancer 1 year before, compared with the PS group ($P < .001$). The changes within each group did not gain statistically significant P values.

Altogether, 84% of the women reported having been given adequate information in the screening invitation, and 79% reported the same about the screening examination. Among women receiving the workup letter and examination, 61% and 72% respectively, were satisfied with the information.

Table 2 shows that more women in the FP group than in the SN group experienced the screening examination either as unpleasant or as both painful and unpleasant ($P < .01$). However, the majority in both groups found it neither painful nor unpleasant.

Table 3 shows that, among the FP group, women who recalled having anxiety about breast cancer 1 year before (prior to the screening), anxiety about the anticipated workup examination, or fear of breast cancer upon receiving the workup recommendation were more likely to have breast cancer anxiety at follow-up, after the reassurance, than those who did not ($P < .001$). Women who were content with the information in the workup letter had a higher prevalence of breast cancer anxiety than those who reported the opposite ($P < .05$). No association was found between the prevalence of anxiety about breast cancer and how the information was perceived at the invitation, the screening, or the workup examination.

Ninety-two percent of the nonattenders and 99% of the attenders and the women never invited indicated willingness to participate in another free mammography screening in the future. Of the attenders, 99% said they would also recommend a similar screening to a friend.

Discussion

The present study shows that a high proportion of women in a general population, approximately one out of three, have anxiety about breast cancer. The results further suggest that having negative results on a screening mammogram decreases this prevalence and that women who elect not to attend a screening are less anxious about breast cancer than those who attend.
